Water quality during shrimp culture in Ponds 1-6 were compared in Fig. 3. Temperature fluctuated 24.3-33.9 °C in nighttime and 28.2-39.0 °C in daytime, and salinity decreased gradually because of the rainfall during rainy season. Biological oxygen demand (BOD), ammonia (NH_4) and turbidity increased gradually during shrimp culture. Water quality sometimes fluctuated because of soil erosion caused by heavy rain and phytoplankton blooming induced by strong sunshine. Water quality was stable throughout the experiment in the control pond (Pond 2), whereas, in the mangrove planted pond (Pond 4), the values fluctuated largely because of the shallow water depth (0.3 m). Dissolved oxygen (DO) decreased during the nighttime and increased in the daytime because of active photosynthesis by phytoplankton. In the daytime of fine days the rate of photosynthesis increased, and so DO and pH increased, and ammonia decreased, while the rate of photosynthesis decreased on cloudy or rainy days.

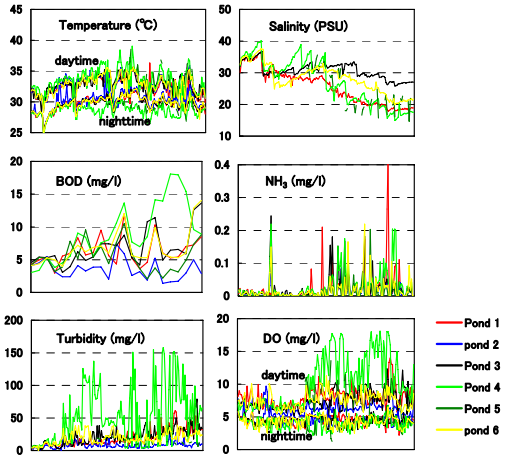

Figure 3: Water quality in experimental ponds during shrimp aquaculture.

Total nitrogen and total phosphorus were compared between before and after the shrimp culture in four modules of the recycling-oriented aquaculture system (Table 1). Before the shrimp culture, 0.001-0.010 mg/l phosphorus and 0.387-1.198 mg/l nitrogen were included in every modules. During the shrimp culture the nutrient increased gradually, and 0.150-0.483 mg/l phosphorus and 1.933-7.565 mg/l nitrogen were included when the shrimp culture terminated. Approximately 70-75 % of nutrient were purified when water circulated from the outlet channel to the inlet channel through the treatment pond; phosphorus reduced from 0.483 mg/l to 0.150 mg/l and nitrogen reduced from 7.565 mg/l to 1.933 mg/l. As the results, up to 2.8 kg phosphorus and 48 kg nitrogen were reduced by means of the recycling-oriented aquaculture system.

When water purified by means of mangrove enclosure, approximately 6.2-8.9 times of ponds was required to reduce the phosphorus (Shimoda *et al* 2005). While, in the recycling-oriented aquaculture system, approximately 5.3 times of areas are required to purify the wastewater, indicating that the system are considerably effective for promoting sustainable aquaculture.

Table 1: Nutrient in recycling-oriented aquaculture system. Total phosphorus and total nitrogen were compared among every modules before and after the shrimp culture. Unit: mg/l

	Total Phosphorus		Total Nitrogen	
	before	after	before	after
Culture pond	0.008	0.230	1.189	3.206
Outlet channel	0.010	0.483	0.610	7.565
Treatment pond	0.001	0.235	0.417	2.041
Inlet channel	0.007	0.150	0.387	1.933

A total of 42 species/taxa were identified from the recycling-oriented aquaculture system. The dominant species belong to three taxonomic categories; that is, (1) free-living nereid, *Perinereis* sp. and tube-dwelling spionid, *Polydora* sp. and some other polychaetes (Annelida), (2) gastropods such as *Cerithidea cingulata*, *Cerithium coralium*, *Sermyla riqueti*, *Stenothyra* spp. which live on the muddy or algal substrata (Mollusca), and (3) barnacles and some small arthropods such as ostracods, copepods, harpacticoids, amphipods and dipterans (Arthropoda) (Fujioka *et al* 2007). Diversity and biomass were the largest in the mangrove planted ponds and water treatment pond because of the diverse habitats associated with the mangrove trees. Whereas, they were smallest in the shrimp culture ponds because the cultured shrimps predated on macrobenthic organisms as food source.

Annelida, Mollusca and Arthropoda were the predominant and most diverse taxa in all the macrobenthic communities in the shrimp aquaculture ponds and the adjacent mangrove ecosystems (Barbier *et al* 2004; Hayashi *et al* 2005; Fujioka *et al* 2007). Since they play important roles under the natural ecosystem; that is, (1) as food for fishery resources in themselves, (2) in the purification of wastewater and sediments, and (3) in degradation, accumulation and circulation of organic materials, we utilize these organisms to maintain and improve the environment for sustainable aquaculture systems.

The results of the shrimp culture experiment were demonstrated in Table 2. During the experimental period, growth rate of shrimps differed largely among individuals from 4.5 g to more than 30 g. Survival rate and production of shrimps were the highest in the water circulated system (Pond 1). Total production of the water circulated system (Pond 1) was approximately 30 % larger than that of the closed system (Pond 2) and, as the results, the feed conversion ratio (FCR) improved about 10 %. In water exchanged system (Pond 6), growth rate of shrimps was very small possibly due to the insufficient improvement of water quality.

Cost performance of the shrimp culture experiment was also compared in Table 2. In the mangrove planted culture system (Pond 4), the artificial feed could be reduced. The profit/cost balance was the highest in the semi-intensive culture system with mangrove trees (Pond 4), followed by the water circulated system (Pond 1) and lower in the closed system (Ponds 3 and 6). Thus, effective aquaculture was achieved in the recycling-oriented aquaculture system such as Ponds 1 and 4.

Table 2: Results of shrimp culture experiment in recycling-oriented aquaculture system.

	Pond 1 Circulated	Pond 3 Closed	Pond 4 Circulated	Pond 6 Exchanged
No. of stocked (A)	13000	13000	6000	13000
Culture density (N/m^2)	20	20	10	20
No. of harvested (B)	4023	2987	1424	3142
Survival rate (%) (B/A)	30.9	23.0	23.7	24.2
Total production (Kg) (C)	58.6	41.5	24.8	25.4
Production (Kg/m^2)	0.10	0.07	0.04	0.04
Average weight (C/B) (g)	14.6	13.9	17.4	8.1
Feed (Kg) (D)	141.3	110.1	42.4	75.5
FCR (D/C)	2.41	2.65	1.71	2.98
Profit (Kg*140bahts)	8790	6225	3720	3803
Shrimp fry (n*0.11bahts)	1430	1430	660	1430
Fuel (Gasoline, Diesel Oil)	910	910	420	910
Feed (800bahts/25kg)	4520	3522	1356	2414
Profit/Cost	1.28	1.06	1.53	0.80

A considerable amount of leftover feed, exuviae and excrement of shrimps, and organic matter derived from the activities of plankton and benthos accumulated on the bottom of the aquaculture ponds and caused anaerobic conditions into the sediments. Cultured shrimp might be stressed by toxic organic materials such as hydrogen sulfide produced during shrimp culture. Such conditions are detrimental for the cultured shrimp and causes low yield of culture production and increase the susceptibility to outbreaks of disease (Barbier *et al* 2004). Controlling and minimizing the negative environmental impact by utilizing biofiltration treatment through the use of natural organisms such as mangroves trees, mollusks, polychaetes, barnacles, seaweeds and plankton is an important practical solution to maintain sustainable shrimp aquaculture.

Reducing the environmental impacts to shrimp ponds should be part of the overall issue of improving the sustainability of shrimp aquaculture. On the basis of a series of our study, we demonstrated a recycling-oriented aquaculture system in Samut Songkhram station as shown in Fig. 4. In this aquaculture model, wastewater circulated from the shrimp culture pond, though an outlet channel, to the water treatment pond. After being purified throughout the convoluted pathway in the water treatment pond, water is recycled to the shrimp culture ponds through the inlet channel. For control of DO, pH and ammonia, the density of phytoplankton should be controlled by means of a biofilter system set beside the inlet channel because they are related to the ability of photosynthesize by phytoplankton.

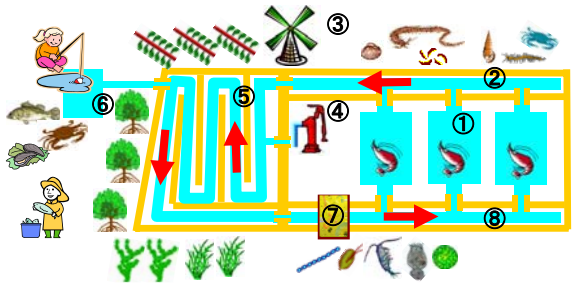

Figure 4: Recycling-oriented aquaculture model utilizing natural ecological functions of benthic and planktonic organisms. (1)shrimp culture ponds, (2) outlet channel, (3) windmill, (4) underground well, (5) water treatment pond, (6) reservoir pond, (7) biofilter, (8) inlet channel

We selected benthic organisms suitable for inhabit the recycling-oriented aquaculture system as follows: 2 mangrove (*Rhizophora mucronata* and *Avicennia marina*), 4 bivalves (*Perna viridis*, *Arcuatula arcuatula*, *Crassostrea belcheri*, *Mytilopsis adamsi*), 4 gastropods (*Cerithium coralium*, *Sermyla riqueti*, *Cerithidea cingulata*, *Stenothyra* spp.), 4 polychaetes (*Perinereis* sp., *Polydora* sp., *Mediomastus* sp., *Laonome albicingillum*), 1 barnacle (*Balanus* sp.), 1 seagrass (*Ruppia maritima*) and 5 algae (*Caulerpa lentillifera*, *Chaetomorpha* spp. *Rhizoclonium* sp., *Acanthophora spicifera* and *Solieria robusta*).

The recycling-oriented aquaculture system utilizing natural ecological functions of organisms was a feasible technology for sustainable aquaculture. For further subject, it is important to carry out the replicated experiments and improve the performance of water/sediment purification with careful screening of benthic and planktonic organisms suitable for this system.

Abstract. The activities of two antioxidant enzymes, superoxide dismutase (SOD) and catalase (CAT), were studied in a colony of *Galaxea fascicularis* corals with increased concentrations of hydrogen peroxide (H_2O_2) in seawater using an incubation chamber. Changes in enzyme activity were compared to those induced by increased seawater temperature. Three H_2O_2 concentrations (0, 0.3, and 3.0 μM) were tested at 27°C, and an elevated seawater temperature of 31°C was tested without added H_2O_2. CAT activities in both coral tissue and zooxanthellae increased with increased H_2O_2, but SOD activities remained relatively unchanged, suggesting that increased H_2O_2 in seawater affected coral cytosol but did not induce superoxide formation. In contrast, the elevated seawater temperature caused both SOD and CAT activities in coral tissue and zooxanthellae to increase. Coral bleaching was not observed at the levels of H_2O_2 tested during the 5-day exposure period. Although the long-term effects of H_2O_2 remain unknown, these results suggest that coral bleaching would likely not occur from short-term (5 days) exposure to increased H_2O_2 concentrations in seawater.

Key words: hydrogen peroxide, antioxidant enzyme, catalase, coral bleaching, *Galaxea fascicularis*

Introduction

In recent years, coral reefs have experienced extensive degradation throughout the world (Stone et al. 1999). This is the result of coral bleaching, whereby corals lose their symbiotic algal zooxanthellae or the photosynthetic pigments of the symbiotes are degraded. The causes of coral bleaching are thought to be abnormally high seawater temperatures, high levels of irradiance, strong ultraviolet (UV) radiation, changes in salinity, or a combination of these factors (Brown 1997; Fitt et al. 2001).

Environmental stress can induce increased production of reactive oxygen species (ROS), leading to significant oxidative damage to the coral-algae symbiotic system (Lesser et al. 1990; Dykens et al. 1992; Downs et al. 2002). The cellular response to the formation of oxygen radicals includes many defense mechanisms (Shick et al. 1995). For example, enzymes such as superoxide dismutase (SOD) and catalase (CAT) act in concert to inactivate superoxide radicals ($\bullet O_2^-$) and hydrogen peroxide (H_2O_2). This prevents the formation of the most reactive form of ROS, the hydroxyl radical (•OH), and subsequent cellular damage (Fridovich 1986). SOD catalyzes the dismutation of superoxide into oxygen and H_2O_2, and CAT is responsible for inactivating H_2O_2 into water and oxygen. These enzymes are responsible for detoxifying ROS, and their elevated activities indirectly indicate increased production of ROS in corals as a result of environmental stresses such as temperature, irradiance, and UV radiation (Lesser et al. 1990).

Smith et al. (2005) hypothesized that H_2O_2 may be the most important ROS associated with coral bleaching because it can act as an important signaling molecule between *Symbiodinium*, i.e., zooxanthellae, and their symbiotic host. In addition, Suggett et al. (2008) reported that the thermal tolerance of *Symbiodinium* is related to adaptive constraints associated with photosynthesis and that sensitive phylotypes are more vulnerable to H_2O_2. Furthermore, Mydlarz and Jacobs (2004) indicated that H_2O_2 production occurred as an oxidative burst in a physically injured *Symbiodinium* sp. that was isolated from *Pseudopterogorgia elisabethae*. Finally, Ross et al. (2006) reported that micromolar concentrations of H_2O_2 (>10 μM) induced cell death in the cyanobacterium *Microcystis aeruginosa* as measured by a caspase protease assay. The production of H_2O_2 was involved in the inhibition of the chlorophyll *a*-chlorophyll c_2-peridinin-protein complexes (acpPC) mRNA translation in *Symbiodinium* (Takahashi et al. 2008). Although many studies have reported the effects of in-cell H_2O_2 on zooxanthellae, few studies have examined the effects of increased H_2O_2 in the seawater surrounding a coral colony.

Here we examined the changes in activities of antioxidant enzymes (SOD and CAT) with varied concentrations of H_2O_2 in seawater and with different seawater temperatures by using a well-controlled incubation chamber. We also compared the magnitudes of changes in enzyme levels induced by H_2O_2 to those induced by high seawater temperature.

Material and Methods

Coral specimens

Colonies of *Galaxea fascicularis* were collected from a coastal region of Okinawa Island, Japan, with permission from the Okinawa prefectural government (No. 18-11). The coral colonies were immediately transferred to an outdoor tank at the University of the Ryukyus Sesoko Station of the Tropical Biosphere Research Center (TBRC). Coral branch tips (ca. 4 cm long) from three large coral colonies were cut and attached to a polycarbonate resin bolt (ca. 1 cm in diameter and 2 cm long) using glue intended for underwater use. The branch tips were kept in the outdoor tank for 3 months, after which they were moved to an indoor tank at the University of the Ryukyus Nishihara campus (ca. 60 km from TBRC) for the enzyme experiments.

Experimental design

We studied changes in coral enzyme activities using a continuous-flow complete-mixing (CFCM) experimental system. The CFCM system consists of a water tank incubation system and a flow-through system, which can continuously supply seawater while maintaining the volume of the seawater in the incubation tank during the course of the experiments. A detailed description of the CFCM is provided by Fujimura et al. (2008).

We investigated the effects of H_2O_2 on the activities of SOD and CAT in coral by controlling H_2O_2 concentrations in the supplied seawater. Various concentrations of H_2O_2 were introduced into the coral incubation tank. The H_2O_2 stock solution was prepared with 0.7 M NaCl + 2 mM $NaHCO_3$ aqueous solution to minimize decomposition of H_2O_2 and changes in salinity and carbonate concentration of the supplied seawater during the experiments. The concentration of H_2O_2 in the stock solution was determined by measuring UV absorbance at 240 nm (ε_{240} = 38.1 M^{-1} cm^{-1}; Miller and Kester 1988). Immediately before the experiments, we prepared 6 and 60 μM H_2O_2 solutions that were diluted 20-fold in the incubation tank to 0.3 and 3.0 μM, respectively. It should be noted that dilution of the filtered seawater was always kept at 20-fold throughout the experiments using the 0.7 M NaCl + 2 mM $NaHCO_3$ aqueous solution even when no H_2O_2 was added.

Seawater temperature was held constant at 27°C, and three H_2O_2 concentrations (0, 0.3, 3.0 μM) were used for 1, 3, and 5-day periods, respectively. In an additional treatment, temperature was maintained at 31°C, and no H_2O_2 (0 μM) was added. Six coral branch tips were used in each treatment. Light was provided by a metal halide lamp, and photon flux density (200 or 0 μmol m^{-2} s^{-1} during a 12:12 h light/dark cycle) was maintained throughout the experiments.

Isolation of zooxanthellae and analyses of antioxidant enzyme activities

Enzyme assays were conducted according to Levy et al. (2006) and Yakovleva et al. (2004). Tissue homogenates were prepared using the air-pick method, in which an air jet connected to a scuba regulator is used to strip the tissue from the coral skeleton into approximately 10 ml of 100 mmol l^{-1} phosphate buffer (pH=7). The volume of the homogenate was measured, and 1 ml of each subsample was used for determination of zooxanthellae density using direct counts on a Neubauer hemocytometer. A 2-ml aliquot of each homogenate sample was filtered using a GF/A filter (Whatman) and used for chlorophyll *a* (Chl. *a*) analysis. Chlorophyll was extracted from the filter overnight with acetone in the dark at 4°C. The absorbance was measured at 630 and 663 nm. We used the Jeffrey and Humphrey (1975) equation to calculate the amount of Chl. *a* extracted from the filter.

The homogenate was further centrifuged twice at 1500 × *g* for 15 min to separate the supernatant and pellets. The supernatant was used to analyze protein and enzyme activities of the host coral. The pellets containing the zooxanthellae were suspended in 2 ml of 100 mmol l^{-1} phosphate buffer, and were then dissolved by sonication for 30 min in an ice bath. A 0.05% Triton X-100 solution was added to the sonicated suspension. After incubation for 10 min, the suspension was centrifuged at 14000 × *g* for 30 min and used as the algal solution for protein and enzyme assays.

SOD activity was assayed spectrophotometrically as described by Elstner and Heupel (1976) and Oyanagui (1984). Standards for activity were prepared using bovine erythrocytic SOD (Sigma) for each set of samples. CAT activity was measured by the depletion of H_2O_2 at 240 nm (Beers and Sizer 1952). All assays were conducted at 25°C, and enzyme activity was expressed as units (U) per mg protein. Protein content was determined by the Bradford assay (Bradford 1976). Dunnett's test was used for the statistical analyses for comparing the data under various conditions against the control data (JMP 6.0.2, SAS).

Results and Discussion

Effects on SOD activity

Figure 1 shows the effects of H_2O_2 and seawater temperature on the activity of SOD in the coral tissue and in the isolated zooxanthellae. With H_2O_2 exposure, there were no significant differences in SOD activity in either coral tissue or zooxanthellae during the 5-day exposure period. Similarly, with a high seawater temperature of 31°C and without added H_2O_2, SOD activity of the host coral was relatively unchanged on day 1 and day 5, even though SOD activity of coral tissue on day 3 was significantly high. Conversely, with high seawater temperature, SOD activity in the zooxanthellae increased significantly by approximately 2-fold on day 3 and day 5 (P<0.01). Increases in antioxidant enzyme activities are indicative of increased concentrations of ROS (Lesser et al. 1990). Given that changes in SOD activity reflect changes in $\bullet O_2^-$ concentrations, the results suggested that H_2O_2 exposure did not induce $\bullet O_2^-$ formation in the coral tissue or zooxanthellae during the incubation period.

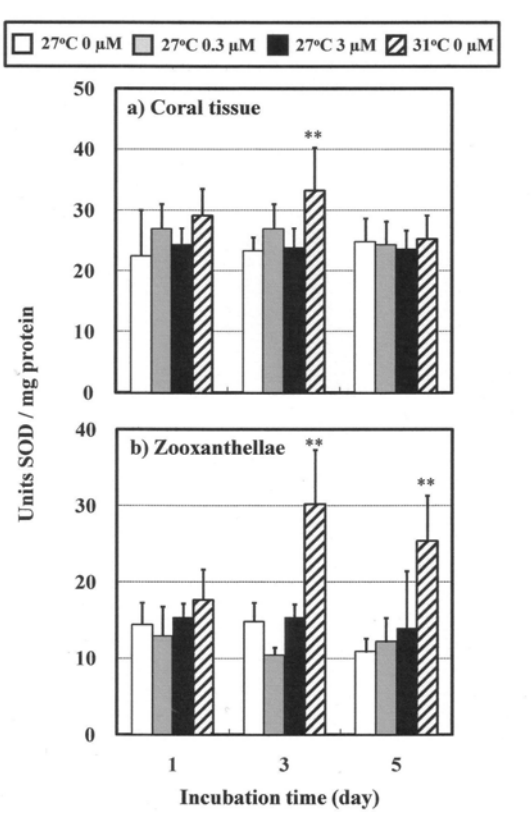

Figure 1: Effects of hydrogen peroxide and/or temperature on the activity of superoxide dismutase (SOD) in (a) coral tissue and (b) zooxanthellae. Means±S.D. (n=6).
**: P<0.01, *: P<0.05 significantly different with Dunnett's test for comparing treatments to a control.

Yakovleva et al. (2004) showed that SOD activity of coral tissue and the zooxanthellae in *Stylophora pistillata* and *Platygyra ryukyunensis* increased under high seawater temperatures, while SOD activity of the coral tissue in *P. ryukyunensis* showed little change. Dykens et al. (1992) suggested that the SOD activity in host coral changed in response to the amount of photosynthetically generated O_2 by its algal symbiotes in the sea anemone *Anthopleura elegantissima*. Our results show a greater increase in the SOD activity of zooxanthellae compared to the coral tissue, which is accordance with these studies and suggests that the zooxanthellae of the coral *Galaxea fascicularis* are more susceptible to temperature changes than the coral host is. In addition, Takahashi and Asada (1983) reported that $\bullet O_2^-$ exhibits low permeability through the cell membrane. Therefore, it is probable that the $\bullet O_2^-$ formed in the zooxanthellae did not penetrate into the coral tissues.

Effects on CAT activity

Figure 2 shows the effects of H_2O_2 and/or high water temperature on the activity of CAT in the coral tissue and in the isolated zooxanthellae. CAT activity was significantly increased by both H_2O_2 and high water temperature in coral tissue and in isolated zooxanthellae (P<0.05).

CAT activities in the host coral and in zooxanthellae increased rapidly within the first day of exposure and were similar for both increased H_2O_2 concentrations and high seawater temperature conditions. Levy et al. (2006) reported that CAT activities increased within a few minutes to several hours. Moreover, as shown in Fig. 2, CAT activities in the coral tissue increased gradually each day with either H_2O_2 exposure or high temperature conditions. It is possible that the coral tissue acclimatized day by day against increased H_2O_2 or high temperature. Yakovleva et al. (2004) also reported that the CAT activities in the coral tissue of *P. ryukyunensis* and *S. pistillata* exposed to high water temperature were higher after 12 h than after 6 h of exposure. CAT activities in zooxanthellae also increased quickly within the first day of the experiments, but CAT activities in zooxanthellae appeared to level off for the remainder of the incubation period. Yakovleva et al. (2004) also reported that CAT activities of the zooxanthellae were slightly lower after 12 h than after 6 h of exposure, which is different from the response of the host coral.

Increases in CAT activities were a result of increased H_2O_2 concentrations in the host coral and zooxanthellae, which suggests that H_2O_2 in the surrounding seawater reached the cytosol of the coral. Dykens and Shick (1982) reported that enzymatic defenses in the animal host occur in proportion to the

potential for photooxidative damage in symbiotic cnidarians. Our results showed that exposing corals to ten-fold differences in H_2O_2 concentrations did not result in significant differences in CAT activities in zooxanthellae, which suggested that zooxanthellae probably had a limit in increasing CAT activities, unless penetration of H_2O_2 into the zooxanthellae was controlled by the cell membrane. Once inside the coral cytosol, H_2O_2 should be inactivated by protective enzymes such as CAT, or could be converted into OH radicals, which could damage the photosynthesis system and can eventually lead to coral bleaching (Levy et al. 2006). Higuchi et al. (2009) showed the photosynthesis rate of the coral *G. fascicularis* was reduced by the higher concentration of H_2O_2. It was suggested that higher H_2O_2 in the coral cytosol remained unless all the H_2O_2 was neutralized by the enzymes because of the limitation of increased CAT activity.

Relationship between ROS and coral bleaching

Figure 3 shows the changes in the density of zooxanthellae, measured as the number of cells per cm^2 of the surface area of the coral colonies, during the 5-day incubation period. There were no significant differences in the density of zooxanthellae with increased concentrations of H_2O_2 during the exposures, even with an addition of 3 µM H_2O_2 (Fig. 3). Thus, coral bleaching was not observed with the elevated H_2O_2 exposure within the 5-day experiments. Downs et al. (2002) suggested that bleaching is a final defense of corals against oxidative stress. As shown in Fig. 2, corals (both host coral and zooxanthellae) were under oxidative stress with increased H_2O_2, but coral was not bleached. This could be because the oxidative stress was not due to the *in situ* formation of H_2O_2 in the symbiotic algae, and therefore the corals did not expel zooxanthellae. Alternatively, it is possible that the oxidative stress posed by the 3 µM H_2O_2 in seawater was within the tolerance level for the tested corals.

Figure 3 also shows the effects of increased seawater temperature on the density of the zooxanthellae. When seawater temperature was elevated from 27 to 31°C, the density of zooxanthellae decreased rapidly by approximately 50% within 1 day, and leveled off for the rest of the 4-day exposure. Significant differences in zooxanthellae density were observed between the corals kept at 27°C and those kept at 31°C during the 5-day high temperature conditions (P<0.05). The amount of Chl. *a* per surface area was also decreased by high temperature (data not shown).

Summary

We studied the effects of increased H_2O_2 in the surrounding seawater and/or high seawater temperature on antioxidant enzyme activities of SOD and CAT in the coral *G. fascicularis*. With increased concentrations of H_2O_2, CAT activities in both coral tissue and zooxanthellae were increased, but SOD activities were relatively unaffected. In contrast, with high seawater temperature, both SOD and CAT activities in coral tissue and zooxanthellae were increased, indicating that both $\bullet O_2^-$ and H_2O_2 were formed within the cell by the increased temperature stress. CAT activities in zooxanthellae were not significantly different even with a ten-fold difference in H_2O_2 concentration. It is possible that the coral tissue and zooxanthellae reached a limit of CAT activity. Coral bleaching was not observed at the levels of H_2O_2 used for our experiments during the 5-day exposure period. Although the long-term effects of H_2O_2 remain unknown, our results suggest that coral bleaching would likely not occur as a result of short-term (5 days) exposure to increased H_2O_2 in the seawater, and that high seawater temperature had a greater impact on the enzymatic activities of the coral.

Abstract. Symbiotic relationships in corals are found to be complex and diverse. The system supports the ecosystem in coral reefs with nitrogen cycles in usually oligotrophic environments. By introducing stable isotopes as carbon and nitrogen into seawater simultaneously, we found that uptake ratios of carbon and nitrogen fluctuate, possibly caused by variation in internal resource availability to the symbiotic system. In this study, empirical data have demonstrated imbalance of nitrogen budget that contributed in the symbiotic relationships with measurement such as nutrients in seawater and nitrogen isotope in corals. The study demonstrated mathematical model based on the findings in the incubation experiment. The model revealed that isotope method overestimate uptake rate by coral symbiosis as only uptake but not excrete rates is considered in the symbiotic relationship. Here, we propose possible method to evaluate internal and external nitrogen cycles in symbiotic system in corals. In the future, the mathematical model is going to be updated as a tool to predict symbiotic complex relationship in corals using new sampling techniques.

Key words: Nutrients, symbiosis, modeling

Introduction

Symbiotic relationships in/on corals enable corals to survive in nutrient-poor environments by exchanging metabolites and photosynthates that contain C, N, and P. Uptake and exchange of nutrients from seawater by zooxanthellae in the coral symbiotic relationships has been studied in the past (D'Elia and Cook 1988; Swanson and Hoegh-Guldberg 1998; Tanaka et al. 2001; Grover et al. 2002; Dugdale and Wilkerson 1986). Recently, the importance of internal cycling was suggested as not only based on the uptake rate but also the release rate for understanding of symbiotic mechanisms in corals (Falkowski et al. 1993).

The objectives of this study are to identify the N resource to symbiotic complex relationship between corals and zooxanthellae, to construct a preliminary mathematical model based on empirical data, and to understand an important process of internal cycling of nutrients as a critical mechanism for abundance of zooxthantellae. Until now, there is very few data on the nutrients concentrations in cnidarians (Fitt et al. 1995). In this paper, we would like to report the first data of nutrient concentration in the internal coral compared with those in seawater. We also intend to propose a new preliminary mathematical model for symbiotic complex relationships between host corals and zooxanthellae.

Material and Methods

Preparation of coral nubbins

Nubbins of 1-2 cm length of *Montipora digitata* and *Galaxea sp.* were collected from shallow water (< 1 m) at Bise, Okinawa, Japan. Nubbins were kept in a tank with running water for at least one week before experimention to minimize impacts of sampling and transportation on nubbins. All containers and instruments were washed with Extran and HCl before they were used for experiments.

Incubation experiment

A nubbin was kept in each 500 ml incubation container. Light intensity was controlled with metal halide lamps. $^{15}NO_3^-$ or $^{15}NH_4^+$, and $H^{13}CO_3^-$ were added to the seawater adjusting the final concentration to 0.07 μM, 0.05 μM, and 0.23 mM, respectively. After 6 hours of incubation period (starting between 5:00 to 7:00 under light), incubation media was sampled for nutrient measurement. Nutrients, NO_3^-, NO_2^-, PO_4^{3-}, and NH_4^+ were measured with TRAACS 2000 (BRAN+Luebbe). Nubbins were removed from the incubation container and tissues on nubbins were obtained using a WaterPik® (Johannes and Wiebe 1970). The tissue slurry was homogenized, and filtered with 47 mm GF/F filter (Whatman). The filter was acidified, dried, and analyzed for isotope ratios in carbon and nitrogen ($^{13}C/^{12}C$ and $^{15}N/^{14}N$).

Nutrient concentrations in coral nubbins

To study nutrient availability in the symbiotic complex in corals, nubbins were ground with a grinder, and 35‰ NaCl solution in Milli-Q water

(NaClaq.) was poured in the grinder. The ground coral skeleton and solution were transferred to a tube. The grinder was rinsed thoroughly with NaClaq. and combined with the solution in the tube. NaClaq. was added to the tube until the volume reached 50 ml. The tube was shaken well, and the supernatant of the tube was filtered with 0.22 μm filter unit (Millipore). Filtrate was stored as a frozen sample for nutrients measurement.

Results

Incubation experiments

The isotope ratio changes in POC and PON from nubbins were directly used to estimate uptake rate from the incubation seawater to symbiosis in corals (Dugdale and Wilkerson 1986, Grover et al. 2003). The isotope ratios of C and N in corals changed after incubation treatment. With $^{15}NO_3^-$ and $^{15}NH_4^+$ treatment, uptake rates were 6.76×10^{-8} M $cm^{-2}h^{-1}$ and 6.66×10^{-8} M $cm^{-2}h^{-1}$, respectively. C/N in taken up by coral nubbins, which was calculated from stable isotope measurement, differed among samples. Enriched with $^{15}NO_3^-$ had higher variability in C/N taken up compared with the treatment enriched with $^{15}NH_4^+$.

Nutrient concentrations in seawater sampled from incubation container decreased in scale of 10^{-2} μM over 6-hour-incubation period.

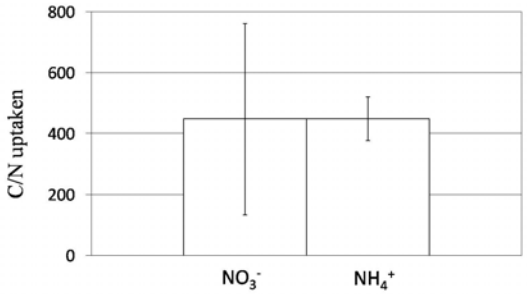

Figure1: C/N taken up by symbiosis in corals over 6 hours. $^{15}NO_3^-$ treatment had higher variation in C/N than that of $^{15}NH_4^+$ treatment. ($^{15}NO_3^-$ treatment (n=5), $^{15}NH_4^+$ treatment (n=6))

Nutrient concentrations in coral nubbins

Higher concentrations of nutrient compared with those of in seawater were detected in nubbins. Especially in nitrate and ammonium concentration in nubbins were about 100 times higher than those in seawater. The concentration varied among samples. During the treatment, nubbins excreted mucus, but the mucus influence is not subtracted from the data.

Table1: Nutrient concentration in seawater and corals. All species was higher in corals compared with those in seawater.

sample	NO_3^-	NO_2^-	NH_4^+	PO_4^{3-}
	(μM)			
Seawater	0.1	0.1	0.39-0.59	0.05-0.08
Corals	1.35-5.21	0.21-0.76	3.88-103.70	0.64-43.52

Discussion

C/N taken up by the coral symbiotic systems were variable, especially with $^{15}NO_3^-$ treatment. This implied that the behavior of C and N used by symbiotic systems in corals is not always the same. It seems that the high concentration of nutrients in nubbins supports an internal resource available besides an external resource (seawater). The high nutrient concentration in the coral symbiotic systems implied that nutrients are regenerated in a symbiotic relationship in corals (Lewis and Smith 1971; Falkowski et al. 1993; Wang and Douglas 1998). Especially the ammonium concentration is considered to be low in cells as such chemical species is detrimental to animals' health in general. Although ammonium might be excreted from corals in form of mucus in this method, the data confirmed ammonium availability in coral symbiotic systems. Whether the symbiotic relationships in corals stock nitrogen as in forms of ammonium or not is unknown. Corals may have a system to synthesize ammonium and incidentally excreting it also as mucus content. Incubation experiments with stable isotopes demonstrated that there were exchanges of nitrogen or carbon between the coral and its symbionts and the seawater even though changes of nutrient concentration in seawater appeared almost inexistant (pseudo state of exchange between surrounding sea water and interior coral). Uptake and exchange of materials from seawater to coral and symbionts has been studied in the past (Tanaka et al. 2001; Grover et al. 2002). Also, the uptake rate by symbiosis in corals has been studied (Dugdale and Wilkerson 1986; D'Elia and Cook 1988; Swanson and Hoegh-Guldberg 1998). In this study, since an internal resource was suggested, not only the uptake rate, but also the release rate was studied in symbiotic relationships in corals in order to reveal masked flow of materials in symbiotic relationships in corals (Falkowski et al. 1993).

Model construction

Here, a simplified model is built to describe symbiotic relationship in coral. In the model, to simplify the symbiotic system in corals, only zooxanthellae and

host corals were selected as symbiotic system. Uptake and release rates were given to each. As such high concentration of nutrients was found in coral nubbins, it was assumed that zooxanthellae take-up nutrients also from the host or in symbiotic systems rather than from seawater only (Fig. 2).

In the model, the host coral takes up nutrients from the surrounding water. As demonstrated in the experiment in this study, there is a possibility that host cells contain much higher nutrients than the seawater. Therefore, the uptake of nutrients by zooxanthellae was considered as uptake of nutrients from the host rather than the seawater. From acquired data and mathematical equations, the exchange rates were estimated. Concentration in seawater, host coral, and zooxanthellae were set to be C*sw*, C*host*, and C*zoox*, respectively.

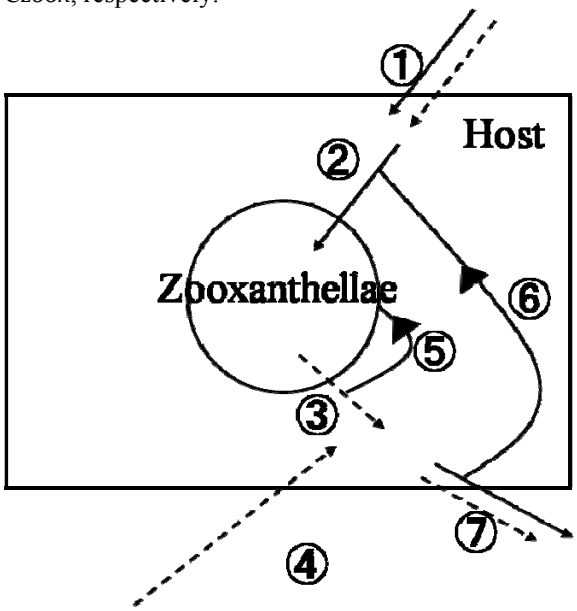

Figure 2: Suggested model of nutrient exchanges in symbiotic complex in corals. Where 1) is uptake of host from seawater, 2) is uptake by zooxanthellae from host tissue, 3) is translocation from zooxanthellae to host, 4) is host uptake of particulate matter from seawater, 5) is allocation of nutrient from zooxanthellae to zooxanthellae, 6) is allocation of nutrient from host to itself, and 7) is release of nutrients and organic matter from host to seawater. Solid arrow is inorganic, and dotted arrow is organic flow.

A mathematical model is constructed to model the nutrient interaction in symbiotic relationship in corals. The model is constructed based on data acquired from the incubation experiment, and from studies in the past. The mathematical model consists of uptake and release. Concentration changes in *s* over incubation period are rates, V*s* ($\Delta Cs/\Delta t$). The changes are integrated from time 0 to time t, then the concentration at time t becomes as the following.

$$Cs(t) = Cs(0) + \int_0^{t1} \{Vs_{uptake}(t) - Vs_{release}(t)\}dt \quad (1)$$

However, the concentration in *s* is influenced by other factors. For example, concentration in the host is influenced by uptake by zooxanthellae and degradation of particulate matter. The equation for host is

$$Chost(t) = Chost(0) + \int_0^t \{Vhost_{\text{uptake}} - Vhost_{release} + Vhost_{\text{deg}} - Vzoox_{\text{uptake}}\}dt \quad (2)$$

where V*host*$_{\text{deg}}$ is degradation rate, V*zoox*$_{\text{uptake}}$ is uptake rate of zooxnatehllae from host cell. When the each rate is integrated, C*host* (t) becomes

$$Chost(t) = Chost(0) + (\alpha - \beta + \gamma - \delta)e^t \quad (3)$$

where α, β, γ, and δ are coefficients for uptake rate, release rate, and degradation rate of particulate matter of host, and uptake rate by zooxanthellae, respectively. V*host*$_{\text{uptake}}$ rate of host was estimated from incubation experiment by using isotope in this study. With this model, major uptake of NH_4^+ from seawater was assumed to be made by host corals (Rees 1987; Miller and Yellowlees 1989). $^{15}NH_4^+$, V*host*$_{\text{uptake}}$ was estimated to be 10.9×10^{-9} mol/cm^2/h after applying the nutrient concentration dependant model, Michaelis-Menten saturation kinetics (D'Elia et al. 1983). Release rate (V*host*$_{\text{release}}$) can be estimated from NH_4^+ changes in seawater and V*host*$_{\text{uptake}}$ with assumption that V*zoox*$_{\text{release}}$ does not directly impact on NH_4^+ concentration in seawater as described in Figure 2.

$$\frac{\Delta[NH_4^+]seawater \times volume}{area \times \Delta t} = Vhost_{uptake} - Vhost_{release} \quad (4)$$

where $\Delta[NH_4^+]_{seawater}$ is NH_4^+ concentration in seawater, *volume* is volume of media used for incubation experiment, area is coral surface area, Δt is incubation time. V*host*$_{\text{release}}$ is estimated to be 11.32×10^{-9} mol/cm^2/h. Here, as uptake and release rates of host are close, isotope method could overestimate uptake rate (Shiroma et al. 2007). From equation (3), by measuring NH_4^+ concentration in host and V*zoox*$_{\text{uptake}}$ *in vivo* (Falkowski et al. 1993), V*host*$_{\text{deg}}$, can be estimated. This first step in mathematical model is useful to understand symbiotic relationship between host coral and zooxanthellae.

The study is needed to scale down the temporal as well as spatial scale to look into complex symbiotic relationship in host corals. Uptake rate for each components needs to be tracked as nutrient assimilation in dark and light are changing (Rees 1987) implying temporal changes in uptake rate. Regeneration of resource in symbiotic complex in

coral is not known in details yet (Falkowsli et al. 1993). Therefore, precise measurement of each component and mathematical model give the allocation rate of nutrient in corals (Swanson and Hoegh-Guldberg 1998). This study limited the symbiotic system by focusing on host coral and zooxanthellae; however, interaction with algae or microbes in symbiotic relationships has been studied today (Knowlton and Rohwer 2003). Empirical data focusing on this scale are needed to develop mathematical model. In addition to degradation of organic matter, the possibility of nitrogen fixation could add some more flow in Fig. 2 (Lesser et al. 2007). Laboratory experiments as well as monitoring *in situ* are required to develop the present model further. Incubation experiment demonstrated that both uptake and release rates need to be measured to estimate nutrient exchange rates in symbiotic relationship in corals. Higher concentrations of nutrients were possibly from coral skeletons, microbes, or symbiotic systems in corals such as mesoglea, stomach, and specific tissues (gastrodermis, ectoderm, or endoderm). New sampling methods will be applied (Agostini et al. 2007) in the future to determine where higher nutrients are distributed or whether the nutrients are directly available to symbiotic complex in corals.

Abstract. The increase in the nutrient level has been suggested as a major cause of localized coral reef degradation. Although the response of corals to nutrients such as ammonium or nitrate is well-documented in laboratory studies, long-term effects of continuously high inorganic nitrogen concentrations on coral physiology remained obscure. To assess the long-term effects of elevated inorganic nitrogen concentrations on the survival and growth of coral colony, we monitored the colonies of two branching reef-building corals *Stylophora pistillata* and *Acropora* spp. that had been exposed to 40 μM of NH_4^+ and 30 μM of NO_3^- over a 12 months period in flow-through aquariums. Both corals showed different responses to nutrient enrichment in survival rate, zooxanthellae density and maximum quantum yield (*Fv/Fm*). These results suggest that although both *S. pistillata* and *Acropora* spp. can adapt to relatively high inorganic nitrogen levels, faster-growing *Acropora* spp. are more susceptible to the increase in nutrient levels. The results also suggest that nutrient enrichment is not an only cause for coral reefs degradation but could results in synergistic impacts when corals are exposed to other environmental stressors.

Key words: eutrophication, growth, inorganic nitrogen, reef-building coral

Introduction

Reef-building corals typically thrive in oligotrophic ocean characterized by low levels of inorganic nutrients. They have adapted to such unique environment by establishing obligate symbiosis with dinoflagellates (zooxanthellae) that can efficiently utilize light energy through photosynthesis (D'Elia and Wiebe 1990). Since nitrogen is a limiting factor for the growth of phytoplankton, symbiotic dinoflagellate *in vivo* take up dissolved inorganic nitrogen (DIN) from surrounding water as well as utilizing coral host metabolites as nutrient sources (Muscatine and Porter 1977; Muscatine et al. 1989).

This symbiotic relationship between corals and algae is easily disrupted by environmental changes which resulted in bleaching phenomena (Hoegh-Guldberg and Smith 1989). Anthropogenic nutrient enrichment impacts on reef-building corals in direct and indirect manners both of which eventually result in the degradation of coral reef ecosystems. Reduction in coral growth and calcification (Marubini and Davies 1996), negative effects on coral reproduction (Ward and Harrison 2000), increase in coral susceptibility to infectious disease and bleaching (Bruno et al. 2003) as well as alteration of benthic community structure in coral reefs (Wielgus et al. 2004) are some of the few documented results of increased nitrogenous levels in seawater.

In contrast to our consensus that reef-building corals can only thrive in low-nutrient concentration water, there are evidences that corals do grow well in relatively high-nutrient water (Atkinson et al. 1995). In addition, a 2-year, large-scale field experiment on the GBR, Elevated Nutrient on Coral Reef Experiment (ENCORE) did not find any major impact of elevated nutrient concentrations on coral reefs at the levels of nutrient loading in areas undergoing eutrophication (Koop et al. 2001). This suggests that there is a possibility of long-term accommodation to elevated nutrients levels by corals and their symbiotic algae, as pointed out by Szmant (2002).

Although effects of elevated nitrogenous levels on corals have been demonstrated in laboratories, most of these studies were short-term (2-3 months) experiments. Among them, many of these experiments aimed at examine the hypothesis of nutrient-limitation in the coral-algae symbiotic association. In this study, we aimed to investigate the effect of elevated nitrogenous level on a relatively long-term survival and physiological changes in two branching, reef-building corals.

Material and Methods

Two species of branching, reef-building corals *Stylophora pistillata* and *Acropora* spp. were used in this study. Colonies of these corals were collected from reefs in the northern Okinawa Island, Japan and

had been acclimatized for more than a year in the flow-through-outdoor tank in Sesoko Tropical Biosphere Research Center (University of the Ryukyus). In July 2007, coral samples were cut into a similar length (approximately 3 cm) and immediately attached to acrylic screws using superglue. The coral nubbins were then acclimatized in an outdoor tank with water flow and allowed to recover for 2 weeks prior to the experiment (Nakamura and Yamasaki 2005).

Twenty four samples of each coral species were selected for the experiments. Twelve samples of each species were placed in both nutrient-enriched and control flow-through tanks (12 cm wide x 53 cm length x 7.5 cm height). Water flow rate was maintained at > 2 cm s^{-1}. Two replicates tanks were set-up for each treatment. Samples were attached to a side wall of the tanks to expose the lateral sides of coral nubbins to sunlight. The nutrient-treated tanks received seawater enriched with NH_4^+ and NO_3^- to give a final concentration of 40 μM and 30 μM, respectively. The control tanks received no nutrient supplement. The concentration of NH_4^+ and NO_3^- in the control tanks were 0.40 μM and 0.80 μM, respectively.

During the period from August 2007 to August 2008, maximum quantum yield of PS II (*Fv/Fm*) were measured weekly in coral nubbins after 15 min sunset. Buoyant weights were measured at the beginning of the experiment and at the end of the experimental period. Nutrient concentrations and flow rate were checked periodically and all tanks were cleaned every week to minimize the proliferation of algae. Data loggers (StowAway, Tidbit) were deployed to record the water temperature variability over the experimental period.

At the end of the experiment, tissue was removed from corals with a WaterPik (Johannes and Wiebe 1970), homogenized and centrifuged at 15,000 x g for 5 min (10°C). The supernatant was then discarded and the remaining zooxanthellae pellets were resuspended in a 10 ml of filtered seawater. Centrifugation was repeated 3 times. Samples were then divided into subsamples for both haemocytometer counts and pigment determination. Chlorophylls were extracted with 90% acetone and kept at 4°C for 48 h in darkness prior to the spectrophotometric determination. Chlorophyll *a* was calculated using the equations described by Jeffrey and Humprey (1975). Coral surface area was estimated using the aluminum foil method (Marsh 1970). ANOVA and *t*-test were used to analyze the data and to evaluate the differences in experimental treatments.

Results

During the course of the experiment, coral nubbins were exposed to a wide temperature ranges: summer 31°C-25°C, autumn 28°C-23°C, winter 23°C-17°C, spring 24°C-19°C. Visible bleaching in *S. pistillata* in both nutrient-enriched and control tanks was observed during summer 2007 and 2008 but not in *Acropora* spp. All bleached samples recovered from bleaching in October 2007. Coral infected by filamentous algae following the bleaching event was 33% in nutrient-enriched samples. However, no filamentous algae infection was observed in the control samples.

Concentrations of NH_4^+ and NO_3^- in enriched tanks were 100-fold and ~38-fold, respectively of those in the control tanks. Differences in coral morphology were observed between the nutrient-enriched samples and the control samples. Corals exposed to elevated nutrient concentrations exhibited darker colouration, larger polyp size, and longer polyp extension period. All coral samples survived throughout the experimental period except *Acropora* spp. that was exposed to elevated nutrient concentrations. Mortality rate was 25%.

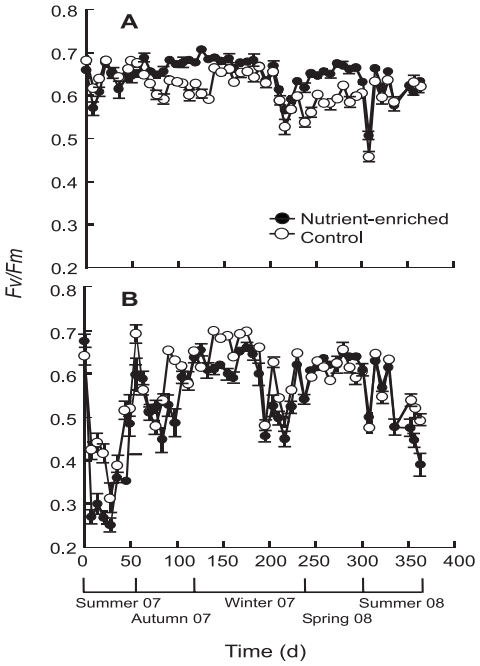

Figure 1: *Fv/Fm* changes in symbiotic algae under nutrient-enriched (filled circle) and control (open circle) conditions throughout the experimental period. (A) *Acropora* spp (B) *S. pistillata* (n = 12, SE = error bars).

Significant difference in *Fv/Fm* between nutrient-enriched samples and control samples were observed throughout the experimental period as shown in Fig 1 (ANOVA, $p<0.01$). *S. pistillata* exhibited a large fluctuation of *Fv/Fm* during the experiment period whereas *Acropora* spp. showed relatively constant

values. Larger fluctuations were observed during summer as well as winter.

Zooxanthellae density in different species of corals responded differently nutrient-enrichment (Fig 2). In the case of *S. pistillata*, significantly higher zooxanthellae density was observed for samples incubated in nutrient-enriched seawater compared to those in control (*t*-test, $p<0.001$). In contrast, in *Acropora* spp., control samples exhibited higher zooxanthellae density than the nutrient-treated samples (*t*-test, $p<0.001$).

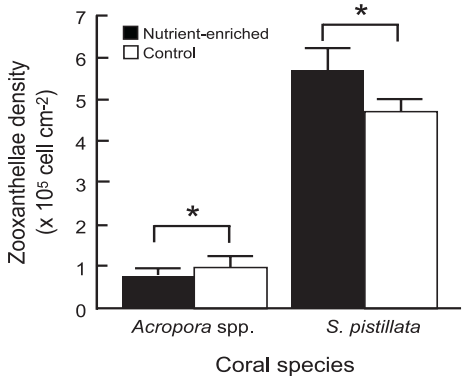

Figure 2: *Acropora* spp. and *S. pistillata*. Number of zooxanthellae per surface area of coral nubbins incubated in nutrient-enriched seawater and control seawater (n = 6, SE = error bars).

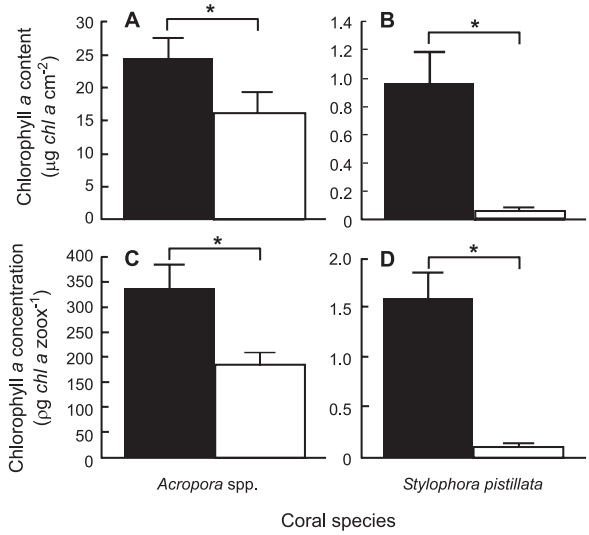

Figure 3: *Acropora* spp. and *S. pistillata*. (A and B) Chlorophyll *a* content per surface area and (C and D) Chlorophyll *a* per zooxanthella for coral nubbins incubated in nutrient-enriched seawater and control seawater (n = 6, SE = error bars).
Note: The y-axis scales are different for *Acropora* spp. and *S. pistillata*.

The most distinct effect of elevated nutrient concentration on the symbiotic algae was the increase in chlorophyll *a* content as shown in Fig 3. Chlorophyll *a* per surface area and chlorophyll *a* per algal cell were significantly greater for nutrient-treated samples compared to control samples (*t*-test, $p<0.001$). The difference between nutrient-treated samples and control samples were 10-fold higher in *S. pistillata* than in *Acropora* spp. Chlorophyll *a* content of *S. pistillata* was significantly lower compared to *Acropora* spp. (ANOVA, $p<0.001$) even though zooxanthellae density of the former was significantly higher than the later (Fig 2, ANOVA, $p<0.001$). These results are concomitant with the low *Fv/Fm* recorded in summer 2008 for *S. pistillata* as shown in Fig 1B.

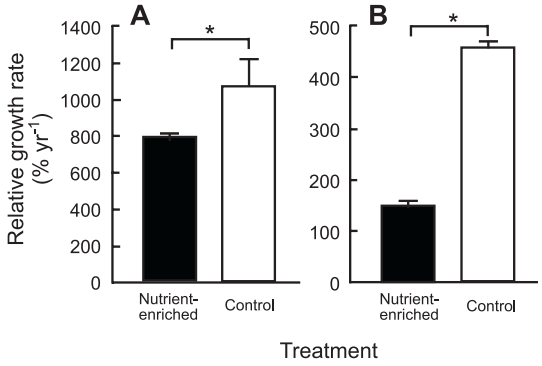

Figure 4: Differences in the relative growth rate over a 12 months period for (A) *Acropora* spp. (B) *S. pistillata* incubated in nutrient-enriched seawater (filled bar) and control seawater (open bar). (n = 6, SE = error bars).
Note: The y-axis scales are different for *Acropora* spp. and *S. pistillata*.

Significantly higher growth rate was observed in control samples than in nutrient-enriched samples (Fig 4, ANOVA, $p<0.001$). Differences in the relative growth rate (RGR) between control sample and nutrient-treated sample for *Acropora* spp. and *S. pistillata* were 1.4-fold and 3.1 fold, respectively.

Discussion

The present study has demonstrated that *Acropora* spp. and *S. pistillata* can survive in conditions of relatively high nutrient levels. However growth rates of corals were negatively affected in the nutrient-enriched treatment. In the short-term (1-2 months) experimental period, more than 50% decrease in the growth of corals exposed to 20 µM of NO_3^- or 20 µM of NH_4^+ was reported (Ferrier-Pagès et al. 2000; Marubini and Davies 1996). However, corals cultured in high-nutrient seawater at the Waikiki Aquarium, Hawaii show similar growth rates compared to those in the field (Atkinson et al. 1995). Coral reefs have formed and flourished under a wide range of natural nutrient regime (Szmant 2002). Given ample time, it is likely that coral and its symbiotic algae have the ability to adapt to relatively high nutrient levels.

Both *Acropora* spp. and *S. pistillata* showed higher chlorophyll *a* content in nutrient-treated samples although the zooxanthellae density was slightly lower in nutrient-enriched samples compared to control samples in *Acropora* spp. General response of corals towards nutrient enrichment include increase in algal density and pigmentation. This resulted in darker colouration in coral tissue (Hoegh-Guldberg and Smith 1989; Muscatine et al. 1989). The symbiotic algae in host can increase their density of thylakoids under elevated nutrient treatment (Berner and Izhaki 1994). This is likely in the case of *Acropora* spp. In contrast, *S. pistillata* might have suffered photoinhibition near the end of the experimental period which resulted in low chlorophyll *a* content.

Effect of nutrient enrichment on coral varies according to coral species. *Acropora* spp. and *S. pistillata* responded differently to nutrient enrichment. Mortality was observed in *Acropora* spp. but not in *S. pistillata*. Although the latter suffered bleaching during summer 2007 (during high SST period), it appears that they are more tolerant to elevated nitrogen level compared to the former. Elevated nutrient concentrations seem to lower the *Fv/Fm* of *S. pistillata* but may have a positive effect on *Acropora* spp. The results suggest that fast-growing *Acropora* spp. may be more susceptible to elevated nutrient levels compared to the slower-growing *S. pistillata*. This result agreed with those reported by Schlöder and D'Croz (2004).

The concentrations of NH_4^+ and NO_3^- used in this study are orders of magnitude higher than in nature as well as on polluted coral reefs. The concentration of NH_4^+ used was lower than the toxic level reported by Hoegh-Guldberg (1994). This is useful for the investigation of effects of elevated nitrogenous levels on the dynamics of coral-symbiotic association, changes in the biochemical composition of algae and long-term survival of corals.

While there are evidences that nutrient enrichment causes negative impact on coral reefs, most of the affected sites have restricted water circulation and the effects are localized (Szmant 2002). Coral nubbins were exposed to constant water flow in this study, which could have lessened the toxic effect of high inorganic nitrogen levels combined with high water temperature (Bouchard and Yamasaki 2008). Water flow reduces photodamage of algal photosynthesis as well as facilitates recovery of coral from bleaching (Nakamura et al. 2003; Nakamura et al. 2005). In general, nutrient enrichment is not the sole factor causing coral reef degradation. Corals exposed to elevated nutrient level become more susceptible to other stressors. This can lead to the decline in coral health and coral reef ecosystem.

Further studies are required in the synergistic impacts of elevated nutrient levels and other environmental stressors on the physiology of corals and coral-symbiotic association. This study suggests that effects of elevated nutrient to corals are species-dependent. Faster growing species may suffer more than slow growing one. This may be due to the differences in adaptation capability of the symbiosis system to changing environment.

Dual-Carbon Sources Fuel the OCS Deep-Reef Community, a Stable Isotope Investigation

Abstract. The hypothesis that phytoplankton is the sole carbon source for the OCS deep-reef community (>60 m) was tested. Trophic structure for NE Gulf of Mexico deep reefs was analyzed via carbon and nitrogen stable isotopes. Carbon signatures for 114 entities (carbon sources, sediment, fishes, and invertebrates) supported surface phytoplankton as the primary fuel for the deep reef. However, a second carbon source, the macroalga *Sargassum*, with its epiphytic macroalgal associate, *Cladophora liniformis*, was also identified. Macroalgal carbon signatures were detected among 23 consumer entities. Most notably, macroalgae contributed 45 % of total carbon to the 13C isotopic spectrum of the particulate-feeding reef-crest gorgonian *Nicella*. The discontinuous spatial distribution of some sessile deep-reef invertebrates utilizing pelagic macroalgal carbon may be trophically tied to the contagious distribution of *Sargassum* biomass along major ocean surface features.

Key words: trophic structure, Gulf of Mexico, OCS reefs, macroalgal carbon

Introduction

Trophic relationships for deep-water communities of the outer continental shelf (OCS) remain poorly studied, particularly in warm temperate and tropical oceans. The present study investigated tissue ^{13}C and ^{15}N stable isotope signatures for the fauna of deep-reef biotopes at 65-120 m on the northeastern Gulf of Mexico (NEGOM) OCS. The objective for this phase of a broader surface-to-substrate ecosystem trophic investigation was to identify carbon sources fueling the NEGOM deep-reef fauna.

Coastal and offshore ecosytems are fueled by organic carbon in the form of dissolved organic carbon (DOC) and/or particulate organic matter (POM) from photosynthesis, sometimes supplemented by chemosynthesis. Terrestrial C3 plants, emergent saltmarsh C4 plants (Thayer et al. 1978), submerged aquatic seagrasses, and benthic macroalgae may also supply carbon to nearshore ecosystems (Thayer et al. 1983). For OCS ecosystems, the only carbon source ubiquitously and continuously available is phytoplankton, classically considered the sole oceanic carbon source (Thayer et al. 1983; Fry and Sherr 1984; Dauby 1989), excluding local primary production from seafloor chemosynthesis (Kennicutt et al. 1985; Paull et al. 1985; Brooks et al. 1987). At high latitudes, sea ice algae may be an important supplementary carbon source (Hobson et al. 1995, 2002). Similarly, benthic macroalgae may contribute carbon to some coastal ecosystems (Dunton and Schell 1982; Stephenson et al. 1984; Simenstad and Wissmar 1985; Dunton and Schell 1987). However, the potential role of pelagic macroalgae as a distinct and important oceanic carbon source has generally been little investigated.

Material and Methods

Study area and sample collection. Sampling was conducted hard-bottom reef areas [ESM: Fig. 1] on the Mississippi-Alabama OCS west of DeSoto Canyon, and the West Florida OCS to the east, during three U.S. Geological Survey (USGS) cruises (2001-2003). Potential carbon sources sampled included near-surface and near-bottom plankton, pelagic macroalgae, and bottom sediment. Holoplankton and POM were sampled simultaneously using horizontal 5-min tows of nested 0.5 m diameter plankton nets, an inner 335 μm mesh net to retain holoplankton, within a 125 μm mesh net to retain POM. Near-surface nets were towed at 3-5 m depth, near-bottom nets at 5-10 m altitude. Bottom sediment was sampled in a 0.0484 m^2 box grab. Consumers sampled included benthic, benthopelagic, and epipelagic fishes and invertebrates. Samples were obtained by angling, fish traps, otter and sled trawls, tangle device, and ROV suction sampler. Macroalgae, attached epibiota, and associated fauna, were obtained in dip nets and 1.0 m diameter plankton nets.

A target of $N \geq 20$ samples per trophic entity was set, attempting to obtain sample sizes sufficient to determine statistically robust isotopic means and standard deviations (Monteiro et al. 1981; Fry and Sherr 1984). Carbon source spectrum analysis

(Jennings et al. 1997) was undertaken when sample N ≥ 20 for a given consumer entity.

Sampling at sea and laboratory preparation. For most fishes a 1-5 g sample of dorsal white muscle was excised, excluding scales, skin and bone. This tissue displays the least variance in ^{13}C and ^{15}N among all fish tissues, and is low in problematic inorganic carbonates and lipids (Pinnegar and Polunin 1999). Slow white muscle turnover rates integrate carbon source signatures over months to years (Hesslein et al. 1993; Post 2002). For invertebrates, a 1-5 g sample of soft tissue was obtained. A 2.0 ml subsample of undisturbed surface sediment was taken from each box grab sample. Outer leaf blades of *Sargassum* spp. (least enriched in ^{13}C: Stephenson et al. 1984, Ishihi et al. 2001) were scraped with a scalpel to remove encrustations, rinsed with de-ionized water (DI), and frozen. *Cladophora liniformis* samples were harvested from *Sargassum*. Plankton samples (excluding fish larvae, chaetognaths, and gelatinous macroplankton) were concentrated into a plug by vacuum filtering through a micropore filter.

Invertebrate tissue and sediment samples were each divided into two portions. One portion was treated with 3N HCl for 48 h to dissolve inorganic carbonates, DI rinsed, centrifuged, dried and plated for assay. Only $\delta^{13}C$ was determined from acidified samples since acid treatment has a significant effect on $\delta^{15}N$ values (Pinnegar and Polunin 1999). All samples were oven-dried at 60° C for 12 h. For $\delta^{13}C$ and $\delta^{15}N$ analyses, a 100 ± 10 μg portion of each ground sample was placed in a foil capsule in a numbered cell in a 96-cell plastic well-plate.

Stable isotope assays. Samples analyzed for $\delta^{13}C$ and $\delta^{15}N$ (N = 1,265) at the University of California-Davis Stable Isotope Facility represented seven potential carbon sources (N = 104 samples) and 107 consumer taxa (N = 1,161 samples) [ESM: Table 1]. The $\delta^{13}C$ reference standard was Pee Dee Belemnite (mean value: -23.83 ± 0.07 ‰, N = 262). The standard for $\delta^{15}N$ was atmospheric nitrogen (mean: 1.33 ± 0.11 ‰, N = 262). Sulfur isotope ($\delta^{34}S$) assays were accomplished at the USGS Menlo Park, California, Stable Isotope and Tritium Laboratory using Canyon Diablo meteoric triolite as the reference standard (analytical precision to < 0.2 ‰).

Trophic guilds. Seven potential carbon source guilds included: near-surface POM (> 125 μm, < 335 μm), near-surface holoplankton (> 335 μm), near-bottom POM, near-bottom holoplankton, bottom sediment, and two pelagic macroalgae (*Sargassum* spp. and *C. liniformis*). Deef-reef consumers were classified into 11 empirically-defined guilds [ESM: Table 1] based on food habits (Weaver et al. 2002): *Sargassum* associates (SA), epipelagic microvores (EMI), epipelagic intermediate macrovores (EIM), benthic particulate feeders (BPF), benthic miniparticulate feeders (BMF), benthic planktivores (BPV), benthic deposit feeders (BDF), benthic microvores (BMI), benthic omnivores (BOM), benthic intermediate macrovores (BIM), and benthic macrovores (BMV).

Two-way ANOVA was used to test the hypothesis that four POM and holoplankton carbon sources did not differ from one another by size fraction or surface versus bottom. One-way ANOVA was performed to test significant $\delta^{13}C$ differences between consumer guilds. If necessary to satisfy ANOVA assumptions of normality and homogeneity of variances, data were log transformed. If ANOVA results indicated significant treatment effects, a Tukey's multiple comparison tested for differences among individual treatments (Sokal and Rolfe 1995). The criterion of statistical difference for all tests was $p < 0.05$. Trophic spectra (Monteiro et al. 1981) were plotted for selected entities (if N ≥ 20) as $\delta^{13}C$ frequency histograms.

Results

Among 114 producers and consumers (N = 1,265 specimens) analyzed for $\delta^{13}C$ and $\delta^{15}N$, sample size of N ≥ 20 was achieved for 21 entities. Only four sediment samples had sufficient mass of organic matter for $\delta^{13}C$ analysis. Ten tissue samples of the benthic planktivorous fish, *Pronotogrammus martinicensis* were analyzed, returning a mean $\delta^{34}S$ value of 19.93 ± 0.55.

Two-way ANOVA contrasts of data for organic carbon source guilds revealed no statistical differences in mean $\delta^{13}C$ between four plankton guilds (near-surface versus near-bottom, and POM versus net holoplankton). Therefore, all four plankton guilds were combined into one overall 'holoplankton' group representing the primary carbon source available to OCS consumers in this study. A t-test revealed no significant difference ($p < 0.05$) in mean $\delta^{13}C$ between the combined holoplankton group and bottom sediment. However, bottom sediment was not grouped with holoplankton as a common carbon source, since it remains unknown if sedimentary carbon becomes resuspensed and available to consumers at depth on the OCS. No significant difference was found between $\delta^{13}C$ means for *Sargassum* spp. and *C. liniformis*, which were accordingly grouped into a single macroalgae producer guild. However, there was a significant difference ($p < 0.001$) in $\delta^{13}C$ data between holoplankton (mean $\delta^{13}C$ = -19.35 ± 1.16‰) and macroalgae (mean $\delta^{13}C$ = -16.41 ± 2.13‰), readily

distinguishing these two different OCS carbon sources (Fig. 1).

Across all consumer samples, $\delta^{13}C$ values ranged from -9.29 to -22.00 ‰, corresponding with the range determined for holoplankton and macroalgae combined (-12.62 to -24.18 ‰), allowing for trophic enrichment. No ^{13}C consumer or sediment signatures indicative of terrestrially-derived POM ($\delta^{13}C \leq$ -26 ‰) (Shultz and Calder 1976) were obtained.

One-way ANOVA contrast in $\delta^{13}C$ data for six benthic invertebrate consumers revealed that the particulate-feeding gorgonian *Nicella* sp. was statistically distinct (mean $\delta^{13}C$ = -15.01 ± 2.17 ‰) from the other five invertebrate consumers analyzed (overall mean $\delta^{13}C$ = -17.29 ± 0.90 ‰) (Table 1). One-way ANOVA contrast of the 11 empirically-defined consumer guilds resolved them into three statistically distinct ($p < 0.05$) consumer groups via $\delta^{13}C$ data, with the BMV and BMF guilds forming two single-guild groups, distinct from a large group comprised of nine guilds of intermediate predators-

Benthic invertebrate consumer	**N**	**$\delta^{13}C$±S.D. (‰)**	**$\delta^{15}N$±S.D. (‰)**
Nicella sp.	30	-15.01±2.17*	9.45±0.55
Argopecten sp.	30	-17.59±0.51	7.17±0.32
Cidaris rugosa	8	-18.93±0.83	8.93±0.53
Plesionika longicauda	17	-16.79±0.48	9.40±1.06
Portunid crab	30	-17.02±0.54	11.10±0.46
Crangon sp.	10	-16.75±1.41	10.22±0.87

Table 1. Comparative $\delta^{13}C$ signatures for six benthic invertebrate consumer entities. * Statistically distinct, $p < .05$.

omnivores (hereafter termed the IPO group) (Fig. 1). Within the IPO group, two guilds, the SA guild and the BPV guild, formed statistically distinct subgroups.

Two of the three major consumer groups form a 1-2-step carbon chain based on holoplankton (Fig. 1). This chain includes all consumer guilds except for the distinctive BMF guild/group, which appears linked to a distinct macroalgal carbon source via a 1-step trophic chain along a parallel $\delta^{13}C$:$\delta^{15}N$ trophic enrichment regression line (Fig. 1).

Statistical contrasts revealed a very small (0.4 ‰), but significant difference between $\delta^{13}C$ means for all pelagic consumers versus all benthic consumers, and between means (Δ = 0.2 ‰) for all epipelagic microvores (EMI) versus all benthic microvores (BMI). However, these differences are negligible compared to the >3.0 ‰ difference in $\delta^{13}C$ up the $\delta^{15}N$ progression, between the holoplankton and

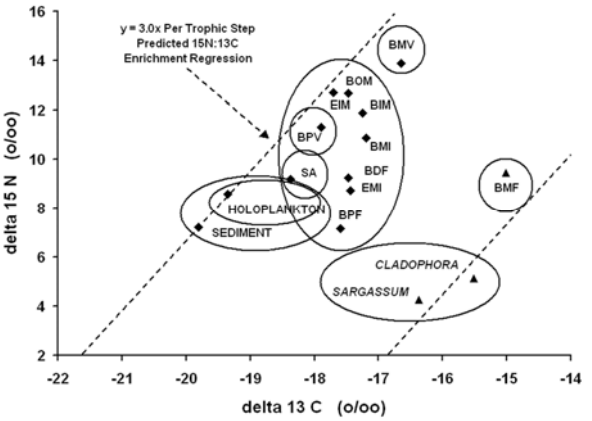

Figure 1: Producer and consumer groups and subgroups (ellipses) defined by mean $\delta^{13}C$ signatures. Abbreviations identify empirically-defined consumer guilds (points are mean $\delta^{13}C$ signatures per guild).

macroalgal trophic chains (Fig. 1). Thus, benthic versus pelagic consumer ^{13}C enrichment (McConnaughey and McRoy 1979; Fry and Sherr 1984; France 1995; Jennings et al. 1997; Pinnegar and Polunin 2000; Hobson et al. 2002) alone cannot account for the enriched $\delta^{13}C$ signatures of *Nicella* or individuals in other benthic taxa (Table 2).

Trophic spectra for most NEGOM deep-reef consumers displayed a sharp unimodal $\delta^{13}C$ peak corresponding with phytoplankton-derived carbon, as in the planktivorous fish *P. martinicensis* (-17.71 ± 0.37 ‰) (Fig. 2). A few consumers such as the planktivorous fish, *Hemanthias vivanus*, displayed a broad $\delta^{13}C$ spectrum (-16 to -22 ‰), but a similar mean (-18.25 ± 1.15 ‰) (Fig. 2). The miniparticulate feeding gorgonian, *Nicella*, displayed a distinctive strongly bimodal $\delta^{13}C$ spectrum (Fig. 2), one mode centered at -16 ‰ (phytoplankton carbon), another at -13 ‰ (macroalgal carbon). Trophic selectivity is

Trophic guild	**N**	**Mean $\delta^{13}C$ range**
Miniparticulate feeders (*Nicella* sp.)	17	-9.19 to 15.87
Sargassum associates	1	-15.92
Epipelagic intermediate macrovores	4	-14.43 to -15.69
Benthic microvores	5	-12.90 to -15.00
Benthic deposit feeders	1	-15.68
Benthic intermediate macrovores	17	-14.12 to -15.95
Benthic macrovores	11	-15.00 to -15.97

Table 2. Consumer guilds containing taxa with individuals (n) yielding notably enriched (≥ -16 ‰) $\delta^{13}C$ signatures.

evident in the comparative spectra of these three syntopic reef-crest particulate feeders, which all feed within a meter of the reef surface. The broad $\delta^{13}C$ spectrum of *H. vivanus* indicates consumption of both POM and larger holoplankton. In contrast, *P. martinicensis* appears to be a zooplankton specialist, while *Nicella* appears to shift between holoplankton versus macroalgae-derived particles, utilizing a carbon source not selected by its competitors.

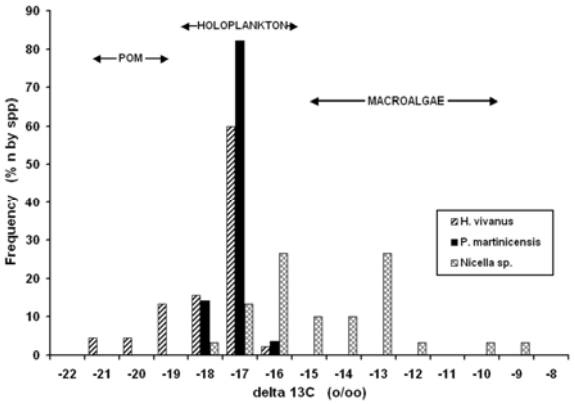

Figure 2. Comparative ^{13}C isotopic spectra (versus probable carbon sources) for three deep-reef particulate feeders: *Hemanthias vivans* (hatched bars) and *Pronotogrammus martinicensis* (black bars), and the gorgonian *Nicella* sp. (cross-hatched bars).

NEGOM OCS carbon sources. No highly depleted $\delta^{13}C$ signatures typical of terrestrial plant carbon (e.g., $\delta^{13}C \leq$ -26 ‰) were observed among the analyzed consumer entities. Additionally, $\delta^{34}S$ values determined for 10 specimens of the benthic planktivorous fish, *P. martinicensis* ranged from +19.20 to +20.89 ‰, (mean +19.93 ‰). These values lie within the range of $\delta^{34}S$ values (+16.6 to +20.3 ‰) previously reported for seawater sulfate, marine plankton, oceanic fish, and offshore consumers (Rees et al. 1978; Peterson et al. 1985, 1986; Fry 1988; Hesslein et al. 1993), providing no evidence of terrestrial sulfur from either C3 plant detritus ($\delta^{34}S$ +4.7 ‰, Peterson and Howarth 1987) or deposited freshwater sediment ($\delta^{34}S$ -14 ‰, France 1995). These ^{13}C and ^{34}S results confirm earlier findings from larval fishes (Thayer et al. 1983), bottom sediments (Shultz and Calder 1976; Eadie et al. 1978), indicating that terrestrial organic input is limited to NEGOM estuarine and nearshore waters (Gearing et al. 1977; Fry and Sherr 1989).

However, findings herein challenge the fundamental assumption that phytoplankton is the sole source of fixed carbon for offshore food webs (Fry and Sherr 1984). Enriched $\delta^{13}C$ signatures ($\geq$ -16 ‰) for individuals in 23 consumer taxa in six guilds (Table 2) provide evidence of a second OCS carbon source. Given a ^{13}C turnover time in fish tissue of months to years (Hesslein et al. 1993), sustained selective feeding on an enriched food source would be required to be reflected in signatures from tissues analyzed (Post 2002). The bimodal spectrum of *Nicella* (Fig. 2) is particularly instructive. The ^{13}C depleted mode at -16 ‰ corresponds with intake of phytoplankton-chain derived particles (holoplankton mean $\delta^{13}C$ = -19.35 ‰), allowing for 1-step trophic enrichment. The enriched mode centered upon –13 ‰ (Fig. 2) suggests intake of particles from a macroalgal source, e.g, *Sargassum* (mean $\delta^{13}C$ = -16.37 ‰) and *C. liniformis*. (mean $\delta^{13}C$ = -15.51 ‰), after one step enrichment.

While oceanic phytoplankton is ubiquitous in time and space, *Sargassum* is discontinuously distributed in both regards. Thus, carbon contributed to tropical and temperate oceanic ecosystems by *Sargassum* would typically be swamped (Parr 1939) in the long-term integrated ^{13}C data presented by most consumer species. Only individuals which have fed on items carrying *Sargassum* carbon for an extended period would display correspondingly enriched $\delta^{13}C$ signatures. A specialist using a trophic switching strategy would display two dominant modes (Monteiro et al. 1981), as seen in *Nicella*. This suspensivore, which inhabits the current-ward crests of deep reefs, appears to selectively switch between particulates derived from macroalgae, or alternatively from plankton-based particulates. Approximately 45 % of the *Nicella* $\delta^{13}C$ frequency distribution (signatures from -9 to –15 ‰) (Fig. 2) appears attributable to macroalgal carbon. A related Mediterranean gorgonian, *Eunicella stricta,* is a specialist deriving most of its carbon from algae and the seagrass *Posidonia*, a refractory carbon source not otherwise utilized by many consumers (Dauby 1989). The $\delta^{13}C$ value reported for *E. stricta* (-14.2 ‰) s close to the mean herein for *Nicella* sp. (-15.01 ± 2.17). Ribes et al. (2003) reported that the gorgonian *Leptogorgia sarmentosa* feeds on a broad range of suspended particles, from nanoeukaryotes < 3.6 µm to zooplankton >100 µm. This species specializes seasonally, utilizing food sources as a function of availability, with a summer minimum in detrital POM use. However, POM accounted for 30.4% of total assimilated carbon. Another gorgonian, *Paramuricea clavata*, derived 48% of its food spectrum from detrital POM (Ribes et al. 1999). A pattern of seasonal selectivity or switching could result in the bimodal $\delta^{13}C$ trophic spectrum of *Nicella* sp.

Parr (1939) estimated the biomass of *Sargassum* in the Sargasso Sea as 3.6-10.0 x 10^9 kg, three orders of magnitude less than estimated phytoplankton biomass for that region. Despite this fact, and the refractory nature of brown algae (Montgomery and Gerking

1980), it seems unlikely that such a biomass of carbon would go unutilized in the world ocean. Present findings suggest it does not. Evidence of selective use of pelagic macroalgal carbon by one deep-reef gorgonian suggests that other OCS reef consumers may depend in part upon this carbon source. Accordingly, their spatial occurrence and abundance may be tied to the predictable concentration of macroalgae along major ocean surface features.

Abstract
Bacterial decomposition of dissolved organic carbon (DOC) in coral mucus was investigated under dark conditions for 7 months to reveal what percentage of the coral-derived DOC is rapidly utilized by bacteria, and conversely, what percentage remained for a long term as refractory organic matter. During the first week, 38%-47% of DOC released from the hermatypic corals *Acropora pulchra* and *Porites cylindrica* were mineralized by bacteria collected from natural reef water. The bacterial abundance dramatically increased from the order of 10^3 to 10^6 cells ml^{-1} during the 1 week. Some part of the remaining organic C at 1 week was slowly decomposed over 3 months, but further degradation was not observed thereafter. Finally, 32%-44% of the initial DOC was not mineralized over 7 months. These results suggest that, under dark conditions, DOC in coral mucus is not completely degraded by free-living bacteria and contributes to long-term C fixation as refractory organic matter.

Keywords: coral, mucus, bacteria, mineralization, refractory organic matter

Introduction

It is well known that coral colonies release organic matter to the ambient seawater as dissolved and particulate organic matter (DOM and POM, respectively) (Tanaka et al. 2008). The coral-derived organic matter is often collectively referred to as mucus. The coral mucus has been regarded as ecologically important: bacterial aggregation was found in coral mucus (Ducklow and Mitchell 1979) and coral exudates actually enhanced the growth of pico- and nanoplankton (Ferrier-Pagès et al. 2000). Wild et al. (2004a, b) showed that a part of coral mucus was rapidly mineralized into CO_2 by bacteria in the reef sediment. The organic matter released from corals has been considered to be a good source of energy for microorganisms and to be completely and rapidly mineralized into CO_2 in the coral reef ecosystem.

However, some studies proposed negative ideas on the bacterial decomposition of coral mucus. Vacelet and Thomassin (1991) observed that coral mucus of high molecular weight (more than 6000−8000) was not completely degraded by bacteria and eukaryotes even after 21 d. Krupp (1984) and Coffroth (1990) concluded that coral mucus itself is a material of low nutritional value for reef organisms and that the property to collect organic detritus and to serve as sites of aggregation for microorganisms is a more important trophic role of coral mucus. More recently, Ritchie (2006) and Chen et al. (2007) found antibacterial substance from coral mucus. These studies suggest that some part of the organic matter released from corals is not rapidly mineralized by bacteria but remain as relatively refractory organic matter.

Therefore, no previous studies have revealed what % of the coral-devied organic matter is rapidly decomposed by bacteria and what % is not. The purpose of this study is to quantitatively investigate bacterial degradability of coral mucus for a long term. Dissolved organic matter in pure coral mucus was put under dark and the change in organic C concentration due to bacterial mineralization was observed over 7 months.

Material and methods

The experiment was performed using two hermatypic corals *Acropora pulchra* and *Porites cylindrica*, which were collected on the reef crest of Shiraho reef in Ishigaki Island (24° 21′-31′ N, 124° 4′-16′ E), Japan in Jul 2007. In Shiraho reef, the reef crest is developed roughly parallel to the shoreline at a distance of ca. 850 m. The corals were collected ca. 700 m offshore, where the depth was ca. 0.5 m at low tide. Six coral branches were cut from several colonies, and put in two glass bottles (i.e., three branches per bottle) for each coral species (total four bottles). The glass bottles (900 ml) contained 300 ml of artificial seawater (ASW). Surface area of each coral branch was 24-53 cm^2 (average 41 cm^2). The water volume was enough to cover the corals. To minimize organic matter contamination in the prepared ASW,

sodium chloride (NaCl), magnesium sulfate ($MgSO_4$), potassium chloride (KCl), and calcium chloride ($CaCl_2$) were combusted at 450˚C for 3 h in advance.

After the collection of the coral branches, the glass bottles were immediately carried to the laboratory. During the transportation, the corals produced much mucus due to the stress of gentle water turbulence in the bottles. Temperature of the seawater in the bottles was same as that of in situ reef water (29-30˚C). In the laboratory, the coral branches were taken out of the bottles. The duration of mucus production was 1 h. 400 ml of ASW was added to each bottle to dilute the produced mucus, and 5 ml of in situ reef seawater was also added to inoculate bacteria in the water column. The sample seawater (total 705 ml for each bottle) was then filtered with pre-combusted Whatman GF/F filters (pore size: 0.7 μm) to remove particulate organic matter (POM) including flocculated coral mucus and expelled zooxanthellae. The filtrate was put in pre-combusted glass bottles (1 L), and the bottles were placed under dark to observe mineralization of DOM in the filtrate. To make same temperature condition, the dark room was kept at 20˚C.

Sampling of the filtrate was conducted at 0, 2, 7, 30, 90, and 220 days of the dark incubation. 15 ml of the seawater was taken into pre-combusted glass ampoules to measure the concentrations of total organic C (TOC) and inorganic nutrients. The ampoules were immediately sealed and stored at -20˚C until analysis. 10 ml of the seawater was taken into acrylic tubes and fixed with pre-filtered formalin (final concentration 2%, v/v) to measure bacterial abundance.

The concentration of TOC was measured by the high temperature catalytic oxidation method (HTCO) using TOC-5000 (Shimadzu). Milli-Q water was used for blank and coefficients of variance for the analysis were <5%. Dissolved inorganic N (DIN: NO_3^-, NO_2^-, NH_4^+) and PO_4^{3-} concentrations were quantified with a nutrient analyzer AACS-III (BRAN+LUEBBE). Analytical error of the nutrient measurement was <0.02 μmol l^{-1}. Duplicate samples from each bottle were analyzed for TOC and inorganic nutrients.

The abundance of bacteria fixed by formalin was counted with an epifluorescence microscopy after staining with SYBR Gold. Bacterial aggregates were disintegrated by weak ultrasonic treatment for 20-30 s. At least 400 bacterial cells were counted from 20-25 fields, except for the samples at t = 0 d. For the samples at t = 0 d, 80-170 cells were counted from >40 fields, due to the small bacterial abundance.

The production rate of DOM (R: μmol cm^{-2} h^{-1}) by the corals was calculated from the organic matter (C: μmol l^{-1}) accumulated in seawater.

$$R = C\,V\,S^{-1}\,T^{-1} \quad (1)$$

where V, S and T are seawater volume (l), coral surface area (cm^2), and the duration of mucus production (h), respectively. Coral surface area was determined by aluminum-foil method (Marsh 1970). ASW used for the experiment initially had minor contamination of organic C (4.8 μmol l^{-1}), compared to the DOC produced by the corals (see below), thus, the C amount was subtracted from all the measured concentrations of TOC at each sampling time, supposing that the initially-contained organic C did not change during the experiment.

Bacterial growth efficiency (E) during the dark incubation was calculated as follows.

$$E = \Delta BC\,(\Delta TOC)^{-1} \quad (2)$$

ΔBC and ΔTOC are an increased bacterial C (μmol l^{-1}) and a decreased TOC (μmol l^{-1}) during a period, respectively. Bacterial C was estimated from determined bacterial number using the conversion factor of 15-30 fg C per bacterial cell (Fukuda et al. 1998).

Results and discussion

DOC accumulated in ASW by the range of 80-97 μmol l^{-1} (Table 1). The release rates normalized to the coral surface area were 400-440 nmol cm^{-2} h^{-1} for *A. pulchra* and 510-650 nmol cm^{-2} h^{-1} for *P. cylindrica* (range of duplicate bottle incubations) (Table 1). The release rates were comparable to those of *Acropora millepora* under the stress of air

Table 1 Initial conditions of the decomposition experiment. 'Conc.' means DOC concentration accumulated in the seawater. Release rates are normalized to the coral surface area. DIN includes nitrate, nitrite, and ammonium. Error bars indicate standard error of analysis

	DOC		DIN	PO_4^{3-}	Bacteria
	Conc. (μmol L^{-1})	Release rates (nmol cm^{-2} h^{-1})	(μmol L^{-1})	(μmol L^{-1})	(10^3 cells ml^{-1})
Acropora 1	80	444	0.86	0.24	4.4±3.0
Acropora 2	84	399	0.92	0.23	2.9±1.5

exposure (980±660 nmol cm^{-2} h^{-1}; Wild et al. 2005). Using the same coral species as the present study, Tanaka et al. (2008) measured DOM and POM release rates from the submerged corals as naturally as possible. The observed DOC release rates were 380 and 340 nmol cm^{-2} d^{-1} for *A. pulchra* and *P. cylindrica*, respectively (Tanaka et al. 2008). Assuming that DOC was continuously released in natural condition at daytime, the release rates of 380 and 340 nmol cm^{-2} d^{-1} would be one order of magnitude lower than those observed in the present study (400-650 nmol cm^{-2} h^{-1}). Wild et al. (2005) also compared the release rates of particulate organic C from *A. millepora* between the corals in air exposure and in a submerged condition, and showed that the release rates under the stress (980±660 nmol cm^{-2} h^{-1}) were about 10 times higher than those in the submerged.

This is the first study which observed the mineralization of DOC released from corals in the time scale of several months. The concentration of TOC dramatically decreased by the range of 32-39 μmol l^{-1} during the first 1 week (Fig. 1). Decreased % was very similar among the four incubations (37%-41%; Table 2). As the organic C was decomposed, NH_4^+ concentration increased from 0.8-0.9 μmol l^{-1} to 5.1-6.1 μmol l^{-1} during the 1 week, indicating that DON released from the corals was simultaneously mineralized. Bacterial abundance increased within the first 2 d by a factor of 1000, i.e. from 10^3 to 10^6 cells ml^{-1} (Fig. 2). Bacterial growth efficiency during the 2 d was calculated to be 12%-37% for *A. pulchra* and 7%-21% for *P. cylindrica*. These are usual values for the growth efficiency of marine bacteria in log phase (4%-30%; Carlson and Ducklow 1996), suggesting that labile organic matter in the coral mucus had similar degradability to that produced in other marine ecosystems, mainly by phytoplankton.

After 1 week, the concentration of TOC slowly decreased until Day 90 (Fig. 1). Average remaining % after 90 d was 37% (Table 2). First order decay constants (*k*) during 7-90 d were 0.004-0.007 d^{-1}, which were one order of magnitude lower than those of the first 1 week (0.066-0.077 d^{-1}; Table 2). After 90 d, TOC concentration decreased only by 1%-4% during the next 130 d (Fig. 1). Average remaining % of organic C after 220 d was 35% (Table 2). *k* values during 90-220 d were 0.0001-0.001 d^{-1} (Table 2). Considering that the decay constants were distinctly different among the three phases (i.e., 0-7 d, 7-90 d, and 90-220 d), the change in TOC concentration in Fig. 1 was not dependent on the concentration but on the different degradability of the organic matter during each phase. It can be defined that the organic matter decomposed during 0-7 d, 7-90 d, and 90-220 d is relatively labile fraction (F_L), semi-labile fraction (F_S), and refractory fraction (F_R), respectively. Supposing that the three defined fractions (F_L, F_S, and F_R) were only mineralized during each period (i.e., 0-7

Table 2 Remaining % of organic C at each sampling time. *k* values are first order decay constants during each decomposition phase.

	Period (d)	Remaining %	k (d^{-1})
Acropora 1	0-7	100 → 59	0.077
	7-90	59 → 32	0.007
	90-223	32 → 28	0.001
Acropora 2	0-7	100 → 53	0.090
	7-90	53 → 35	0.005
	90-223	35 → 33	0.0004
Porites 1	0-7	100 → 62	0.069
	7-90	62 → 37	0.006
	90-222	37 → 35	0.0003
Porites 2	0-7	100 → 63	0.066
	7-90	63 → 44	0.004
	90-222	44 → 43	0.0001

d, 7-90 d, 90-220 d), the percentage of each fraction can be calculated from the decreased % in Table 2: F_L, F_S, and F_R accounted for 37%-47%, 19%-26%, and 32%-44%, respectively (on average, F_L: 41%, F_S: 22%, F_R: 37%). Adding up F_L and F_S, about 60% could be mineralized by the bacteria within 3 months.

The present study has quantitatively shown that a part of the organic matter released from the corals is not mineralized into CO_2 by free-living bacteria in the reef water. There existed some inorganic nutrients in the incubated seawater at the end of the experiment (t = 220 d): 7.8-10.2 μmol N l^{-1} and 0.38-0.55 μmol P l^{-1}. Thus, bacterial incorporation of the remaining organic C could not be limited by the availability of N and P. Some possibilities are suggested for the remaining organic C. First, the organic matter released was originally recalcitrant to bacterial decomposition. Using coral mucus with molecular weight larger than 6000−8000, it was observed that the mucus web was not completely degraded by bacteria and eukaryotes even after 21 d (Vacelet and Thomassin 1991). They explained that mucus excretion from coral is a defensive reaction against physical and chemical stresses, thus mucus is a poor, or even inhibiting medium for the bacterial degraders isolated from the mucus itself. Similar results were also reported by Pascal and Vacelet (1981). Krupp (1984) and Coffroth (1990) also suggested that coral mucus is a material of low nutritional value for reef organisms. More recently, Ritchie (2006) observed that mucus from *Acropora palmata* had antibiotic properties that were likely to play a role in ordering only beneficial microbial communities on the coral surface. Antibacterial substance was also found from coral mucus of *Symphyllia gigantea* (Chen et al. 2007) and from tissue extraction of some soft corals (Kelman et al. 2006). Coral colonies might routinely produce organic matter resistant to the degradation by bacterial communities in the water column.

The second possibility explaining the remaining organic matter is that coral-derived organic matter was once utilized by bacteria and converted into different organic forms, which were recalcitrant to further bacterial decomposition. Ogawa et al. (2001) reported that when marine bacteria utilized labile compounds (glucose, glutamate), they produced refractory DOM (R-DOM) that persisted for more than a year. Their result suggested that microbial processes alter the molecular structure of DOM, making it resistant to further degradation. Considering that 5%−7% of original substrate C (glucose, glutamate) were altered to R-DOM in Ogawa et al. (2001), R-DOM produced by bacteria in the present study could account for only a minor part of the remaining organic matter (Fig. 1 & Table 2), supposing that the bacteria produced R-DOM with the similar ratio. Therefore, the preservation of the organic matter in the present experiment (ca. 35%) could not be explained only by bacterial activity to produce R-DOM, but some parts of the remaining organic matter could originally have resistance against bacterial decomposition.

Wild et al. (2004a, b) pointed out the important role of bacteria in reef sediment to decompose coral mucus. They considered that a highly diverse and dense sedimentary bacterial population, adapted to the decomposition of more refractory material, can decompose coral mucus more effectively than the bacterial community in water column. Because only the bacteria in water column were inoculated in the present study, the possibility that sedimentary bacteria decompose the remaining organic matter needs to be investigated in the future. However, a part of coral-derived organic matter could diffuse and be exported to the outer ocean without settling down to the sediment, especially in the reef where water residence time is short. For example, in the study site of the present study (Shiraho reef), average residence time of the lagoon water was estimated to be 4-8 h (H. Yamano unpubl. data). Hata et al. (2002) concluded that 6%-7% of gross primary production in Shiraho reef was exported to the outer ocean as POC. Their study also suggested the export of DOC from the lagoon. The present paper showed that considerable parts of the exported DOC might remain as refractory organic matter over several months.

Abstract. A new NOAA tropical coral bleaching outlook system has just been developed. The system includes a sea surface temperature (SST) prediction model based on NOAA's Linear Inverse Model (LIM) and a bleaching thermal stress model based on the coral bleaching HotSpot and Degree Heating Week (DHW) algorithms used in NOAA Coral Reef Watch (CRW) operational near-real-time satellite bleaching monitoring. The system forecasts regions of potential thermal stress conducive to coral bleaching ranging from one week to 18 weeks in advance.

Key words: Coral bleaching, Thermal stress, Prediction, Forecast, Outlook.

Introduction

Mass bleaching of coral reefs has occurred with increasing frequency in recent decades. The US National Oceanic and Atmospheric Administration's (NOAA) Coral Reef Watch (CRW) provides critical information to reef managers and scientists based on near-real-time satellite monitoring of thermal stress conducive to coral bleaching (Liu et al. 2006). However, many managers and scientists have requested information on the likelihood of coral bleaching months in the future.

NOAA CRW, in collaboration with the Physical Sciences Division of the NOAA Earth System Research Laboratory (ESRL), has just developed a bleaching prediction tool capable of forecasting weeks to months in the future. Using global sea surface temperature (SST) forecast models, NOAA CRW now provides outlooks of potential bleaching thermal stress, to significantly improve strategic planning and management of coral reef ecosystems. Here we introduce this bleaching outlook system and evaluate its performance by comparison with CRW operational near-real-time observations.

Bleaching Outlook System

The NOAA bleaching outlook system covers the tropical latitudes between 30ºS and 30ºN. The outlook comprises three integrated parts: sea surface temperature (SST) prediction model, coral bleaching thermal stress prediction, and coral bleaching outlook. The SST model results are currently available at 2º×2º ×weekly resolution and for lead times of 1 to 24 weeks. The seasonal bleaching outlook is created from the maximum thermal stress forecast up to 18 weeks into the future.

Sea Surface Temperature Prediction Model

The system uses the SSTs predicted by the NOAA Linear Inverse Modeling (LIM) developed by NOAA/ESRL Physical Sciences Division (Penland and Matrosova 1998; Penland and Magorian 1993; Penland 1989). LIM is a statistical derivation of the best dynamical description from the observations of a linear system and prediction are made from the derived statistical model. Penland and Sardeshmukh (1995a) and Penland and Matrosova (1998) found that the evolution of tropical SST anomalies (SSTAs) can in large part be represented as a stable, multivariate linear dynamical system maintained by stochastic forcing. From this, NOAA developed the NOAA LIM prediction model for forecasting tropical SSTAs.

Weekly 1º×1º Reynolds and Smith Optimum Interpolation SST (OISST) data (Reynolds et al. 2002 and 1994) between 30°N and 30°S during the years 1982-2006 were consolidated onto 2º×2º grids to train our model. This minor reduction in spatial resolution reduces the number of degrees of freedom one must diagnose from a fairly short data set. Then, weekly climatologies were derived and weekly SSTAs were calculated. The resulting anomalies were cast in terms of Empirical Orthogonal Functions (EOFs). Most of the variability and almost all of the predictable variability were compressed into a basis having a much smaller dimensionality than the original data. The leading 30 EOFs that contain 75% of the data are retained in the model. Using this compressed

description of the data, LIM was applied to estimate the linear operators giving the best forecast of SSTA.

Prediction of global tropical SSTAs is made by applying the statistical model described above to the observed initial SSTAs as represented by EOFs from weekly OISST. The prediction in the EOF domain is then cast back to SSTA in the geospatial domain. Both initial conditions and forecasts have smaller amplitude than the original data because, on average, only 75% of the variance was retained. To account for this reduction, predicted anomaly at a location is inflated by a factor reflecting the amount of variance retained at that location. For example, SSTAs in a location where only half the variance is retained are inflated by the square root of 2, while very little is inflated in a region that retained nearly 100% of the variance. The climatology is added to the adjusted prediction of the SST anomaly to give the SST forecast.

Bleaching Thermal Stress Prediction Model

The stress forecast methodology is similar to the CRW operational near-real-time satellite coral bleaching monitoring. In the near-real-time monitoring, the HotSpot measures the intensity of bleaching thermal stress as the difference between the observed SST at a grid point and the climatologically averaged temperature for the warmest month. Since both intensity and duration of thermal stress are important in causing bleaching, the Degree Heating Week (DHW) accumulates HotSpot values ≥1.0 ºC during the prior 12 weeks (Liu et al. 2006). DHWs of 4 ºC-weeks is likely to cause significant coral bleaching, and 8 ºC-weeks or above is likely to cause widespread severe bleaching and significant mortality (Liu et al. 2006).

Similarly, in the stress forecast, the HotSpot prediction is calculated as the difference between the model-predicted SST and the climatologically averaged OISST temperature for the warmest month. In deriving DHW prediction, we found that a threshold of 0.5 ºC of predicted HotSpot for accumulating DHW prediction yielded the best agreement between the predicted DHW and CRW's near-real-time DHW observation. This lower threshold is a consequence of reduced amplitude of SST variation intrinsic to the LIM model and a reduced spatial and temporal resolution in the outlook relative to CRW near-real-time observations. Weekly bleaching thermal stress predictions are produced for the upcoming 18 weeks.

Coral Bleaching Outlook Model

A coral bleaching outlook algorithm was developed to derive a bleaching risk level from the predicted thermal stress. Three levels of bleaching risk are defined based on the relationship between the hindcast HotSpot and DHW for 2001-2007 and the HotSpot and DHW observations from archived 2001-2007 near-real-time satellite data. The three levels are color-coded on an outlook map (Fig. 1) and defined as:

Potential Bleaching (light-orange):
$HS_{pred} > 0$
Potential Widespread Bleaching (orange):
$HS_{pred} > 0.5$
Potential Severe Bleaching (brown):
$HS_{pred} > 0.5$ and $DHW_{pred} > 4$

where, HS_{pred} and DHW_{pred} are HotSpot and DHW predictions, respectively. A seasonal outlook of bleaching potential for the upcoming 3 to 4 months is based on the maximum composite of weekly outlooks in the predicted seasonal time period.

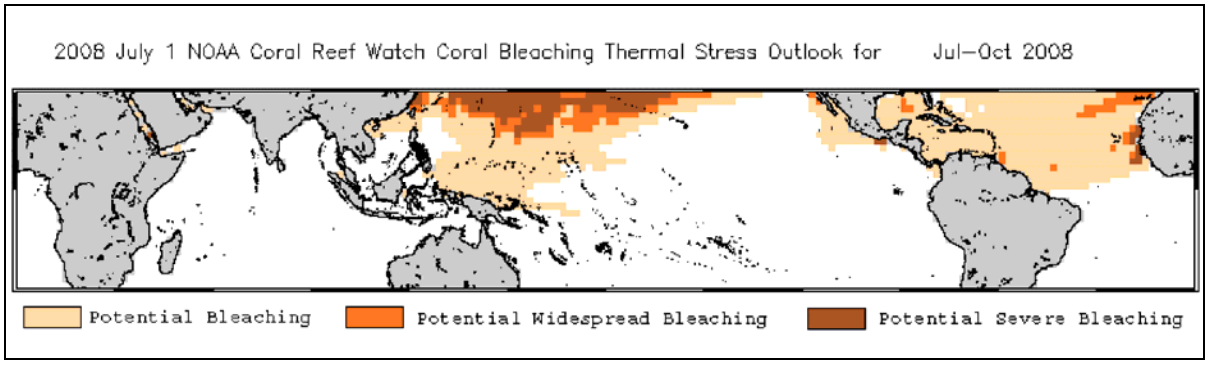

Figure 1: Seasonal bleaching outlook for July-October 2008 produced on July 1, 2008

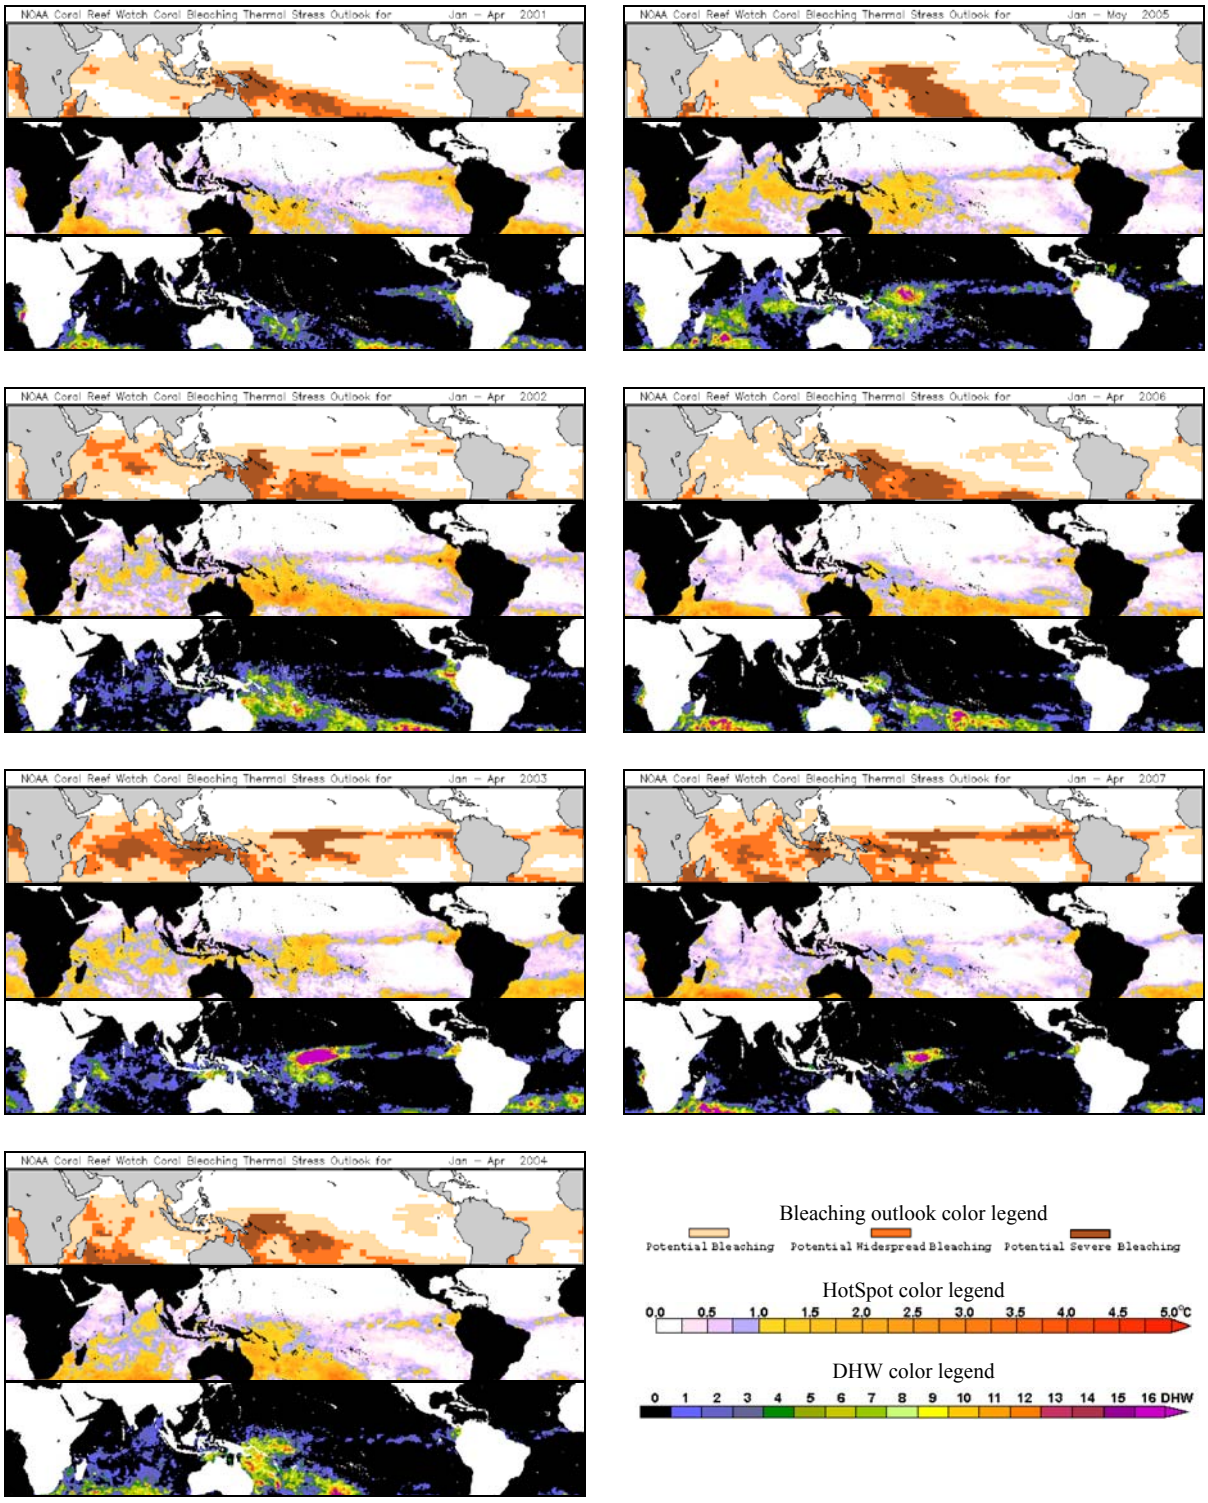

Figure 2: Hindcast austral bleaching season (January-April) seasonal bleaching outlooks for 2001-2007 (top panel of each three-panel set one for each year) and the maximum composites of the CRW near-real-time twice-weekly satellite HotSpot and DHW observations for the corresponding time periods (middle and bottom panel of each three-panel set).

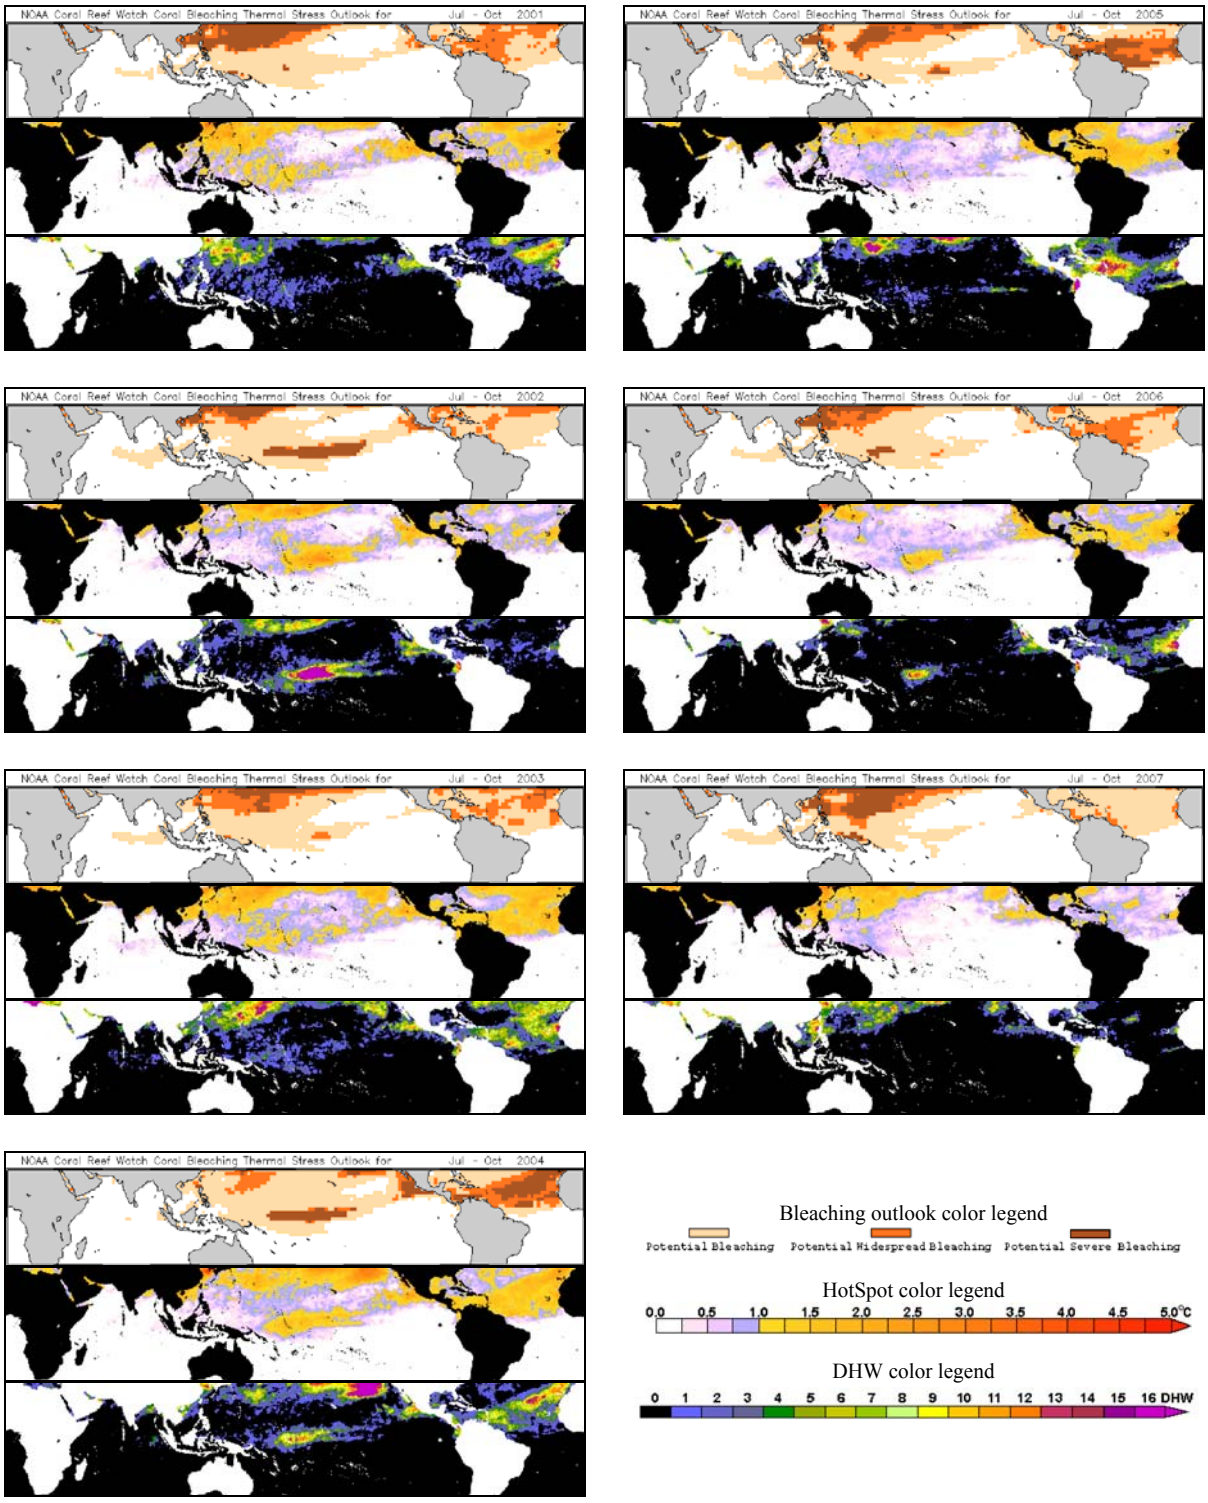

Figure 3: Hindcast boreal bleaching season (July-October) seasonal bleaching outlooks for 2001-2007 (top panel of each three-panel set one for each year) and the maximum composites of the CRW near-real-time twice-weekly satellite HotSpot and DHW observations for the corresponding time periods (middle and bottom panel of each three-panel set).

Analysis of Seasonal Bleaching Outlook Products

We have examined the accuracy of the seasonal bleaching outlook product during a 7-year set of boreal and austral bleaching season predictions. Seasonal bleaching outlook maps for January-April and July-October of 2001-2007 are shown (Fig. 2-3)

together with the maximum composites of the CRW operational near-real-time twice-weekly HotSpot and DHW observations for the corresponding time periods. This corresponds to seven full years during which has operated its Here we compare the outlook and monitoring data for the Caribbean, Great Barrier Reef (GBR), and Northwestern Hawaiian Islands (NWHI) during known large-scale bleaching events.

The general pattern and intensity of the seasonal bleaching outlooks match well with the HotSpot and DHW observations. For the GBR region (Fig. 2), the 2002 mass bleaching event (Oliver *et al.* 2008) is well captured in the seasonal outlook. The outlook correctly predicts low to mild stress years at the GBR for 2001, 2003, 2005, and 2007, but over-estimates the thermal stress in the GBR for the 2006. For the Caribbean region (Fig. 3), the outlook performs well for all seven years, including the 2005 mass coral bleaching event (Wilkinson and Souter 2008). HotSpot and DHW observations show that in all years, high thermal stress was seen in the northwestern Pacific Ocean near the NWHI (Fig. 3). Mass coral bleaching occurred in the NWHI 2002 (Aeby et al. 2003) and 2004 (Kenyon and Brainard 2006), suggesting the outlook underestimated the stress for these two events. However, the outlook tended to overestimate for other years where thermal stress was comparatively low.

Discussion

The comparison for 2001-2007 shows that the seasonal bleaching outlooks generally match the HotSpot and DHW observations. The outlook performs best in the Caribbean and GBR regions, but does not perform as well in the NWHI. This may be caused by relatively low variance explained by the leading 30 EOFs around the NWHI, but we are continuing to investigate. Also, unlike the Caribbean and GBR, masses of warm water are not constrained by land-masses and may easily miss these small islands. Examination of weekly predictions (not shown) also indicates that these are able to predict the development and dissipation of thermal stress during mass coral bleaching events, including the record-breaking 2005 bleaching in the Caribbean.

As with any forecast model, both the variance and accuracy decline with longer lead times. In the case of this outlook product, it tends to increasingly underestimate the thermal stress at longer lead times. It also seems to develop unrealistically high thermal stress at short lead times near the end of the bleaching season. These suggest that predicted HotSpot values may need to be calibrated as a function of lead time. NOAA CRW will continue to evaluate this new prediction system to improve the accuracy for coral reefs globally.

This new NOAA bleaching outlook system has been available at CRW's website, http://coralreefwatch.noaa.gov, since July 2008. It is updated weekly to provide coral reef managers and researchers critical information on large-scale bleaching thermal stress events weeks to months in advance. Similar to seasonal hurricane outlooks, the outlook product does not to provide exact predictions at any particular reef locations, but provides general patterns of potential bleaching, enabling managers and scientists to prepare in advance.

Recovery of *Diadema antillarum* and the potential for active rebuilding measures: modelling population dynamics

A. Rogers, K. Lorenzen

Division of Biology, Imperial College London, Silwood Park, Ascot SL5 7PY, United Kingdom

Abstract. Recent studies suggest that population recovery of the long-spined sea urchin *Diadema antillarum* could help to reverse the phase shift observed on Caribbean coral reefs by reducing macroalgal cover and promoting coral recruitment. Interest has arisen around the potential for active rebuilding measures such as hatchery release and translocations to aid and increase the slow and patchy population recovery so far witnessed since the 1983 mass mortality event. We developed a population dynamics model for *D. antillarum* to gain insight into the key processes preventing population growth and assess the effectiveness of proposed rebuilding strategies. The model accounts for compensatory density-dependence in recruitment and growth and depensatory density effects associated with fertilization success, a possible refuge function of the adult spine canopy for juveniles and 'cultivation' of preferable habitat by grazing. Results show that the population can exist at low and high-abundance equilibria associated with high and low macroalgal abundance respectively. The switch to high abundance is hampered by high juvenile mortality due to the absence of refuges. Restoration may be aided by release of large urchins and by manipulation of macroalgal cover. Experimental work is suggested to test process models and quantify functional relationships used in this exploratory analysis.

Key words: Allee effect, cultivation effect, predation refuge, habitat modification, active rebuilding

Introduction

The long-spined sea urchin *Diadema antillarum* was once abundant on coral reefs of the Caribbean region, fulfilling a role as the keystone herbivore of macroalgae (Sammarco 1982; Carpenter 1986). Its functional extinction following the mass mortality event of the early 1980s had a profound effect on coral reef community composition and is thought to have played a major role in the subsequent phase shift from states dominated by live coral to states dominated by macroalgae (Aronson and Precht 2000). Recent studies have shown that population recovery of *D. antillarum* has the potential to reverse the phase shift, reducing macroalgal cover and promoting coral recruitment (Edmunds and Carpenter 2001; Carpenter and Edmunds 2006). Widespread population recovery of *D. antillarum* may therefore be considered as a tool with which to aid coral reef restoration in the Caribbean.

While in some locations, *D. antillarum* abundance has recovered markedly (Carpenter and Edmunds 2006); in others the population has persisted at a low level of abundance (Lessios 2005; Chiappone et al 2002). The mechanisms underlying differential recovery and the potential for active rebuilding measures remain poorly understood. Hypotheses relating to the negative impact of low population density on population growth may explain the slow and patchy recovery that has been observed across the region (Lessios 1988). *D. antillarum* is a dioecious species with broadcast spawning, a long larval stage and limited adult dispersal (Lessios 1988). Despite their long spines, *D. antillarum* are susceptible to predation by around 15 fish species and multiple invertebrates with the greatest risk being to smaller size classes (Carpenter 1984; Clemente et al 2007). Direct negative effects of low population density, referred to as Allee effects may be responsible for a reduction in fertilization success, larval settlement and post-settlement survival (Bak 1985; Levitan 1991; Miller et al 2007). At low population density the chances of adult urchins spawning synchronously and at close enough proximity to allow for successful fertilization is greatly reduced (Levitan 1991). Larvae in the water column may take settlement cues from conspecifics and it is thought that the spine canopy of adult urchins may act as an important predation refuge for susceptible juveniles (Nishuzaki and Ackerman 2007; Miller et al 2007). Both larval settlement and post-settlement survival may be further reduced at low population density through an indirect effect which we will refer to as the cultivation effect.

As prolific grazers and bioeroders, *D. antillarum* are associated with habitats low in macroalgal cover and high in reef topographic complexity (Lee 2006). Evidence suggests that surfaces clear of macroalgae are preferred for larval settlement (Bak 1985) and we hypothesize that reefs that lack macroalgae and have greater topographic complexity will naturally have more reef cracks and crevices that provide effective predation refuges. Few studies have set out to test hypotheses relating to Allee and cultivation effects and none have aimed to quantify their impact at a demographic level. In this study we synthesize data from the literature and use it to produce a combined population dynamic and grazing impact model for *D. antillarum.* The aim of the modeling process is to gain a quantitative understanding of the recovery dynamics of this keystone species and inform the best avenues for future empirical studies and rebuilding strategies.

The model was explored to assess the impact of Allee effects and cultivation effects on the critical densities and sizes of urchins required for population persistence and population growth. The model was run under circumstances of both initial high macroalgal cover and low macroalgal cover to examine the impact of potential habitat modification.

Methods

We produced a combined population dynamics and grazing impact model for *D. antillarum.* Population dynamics are described by a size-structured, projection matrix model (Shepherd 1987; Lorenzen 1995) in which, the urchin population is divided into size classes such that the population density at time t is represented by a vector, n of densities-at-size. The equation that computes this vector for time $t + dt$ is:

$$n_{t+dt} = GS(n_t + r_t) \qquad (1)$$

Where G is a growth projection matrix, S is a survival matrix and r is a vector of new recruits obtained from the stock-recruitment relationship described below. Both G and S are dependent on population density and habitat state.

Growth

Due to conspecific competition for resources, *D. antillarum* exhibit density-dependent indeterminate growth, such that growth rates and asymptotic sizes decline with increasing population density. Growth in the model population is therefore described by a density-dependent extension of the von Bertalanffy growth function (VBGF) as described by Lorenzen (1996a) such that the diameter of urchin $D_{\infty}(B)$ is a linear function of biomass B:

$$D_{\infty}(B) = (D_{\infty L} - dB) \qquad (2)$$

Where $D_{\infty L}$ is the limiting asymptotic diameter in the absence of resource competition and d is the competition coefficient. This growth rate equation is used to produce the growth projection matrix, G by the method described by Shepherd 1987.

Mortality

The annual mortality rate, M in the model population is the sum of size-dependent baseline mortality excluding predation, M_b and additional predation mortality M_p.

$$M = M_b + M_p P_1 P_2 \qquad (3)$$

Baseline mortality, M_b is a function that describes the inverse relationship between individual size and mortality (Lorenzen 1996b). Predation mortality, M_p is a vector of values that describes additional size-dependent predation mortality. The values of M_p are estimated from a recent study that used a tethering experiment to show that predation risk was greatest in the smallest size classes and non-existent after a threshold size of 40mm (Clemente et al 2007) (Fig. 1).

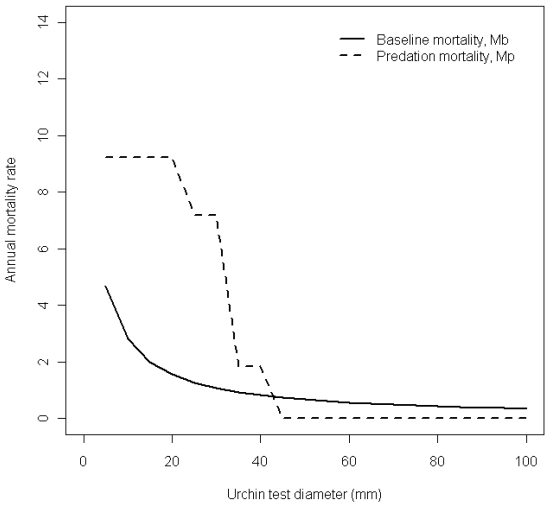

Figure 1: The shape of the relationships used to describe baseline mortality, Mb (Lorenzen curve) and predation mortality, Mp from Clemente et al 2007.

Due to the artificial nature of tethering experiments, the values assigned to M_p are considered to represent maximum levels of predation mortality.

Predation mortality is moderated by two parameters P_1 and P_2 which represent predation refuge effects associated with the hypotheses described previously, the adult spine canopy and the cultivation effect. P_1 is a function of adult surface area and acts such that predation risk, M_p declines as adult surface area and

thus spine canopy increases (Fig. 2a). P_2 is a function of macroalgal biomass and acts such that predation risk, M_p increases as macroalgal biomass increases (Fig. 2b). In this instance, macroalgal biomass is the variable used to represent the link between habitat cultivation and refuge availability.

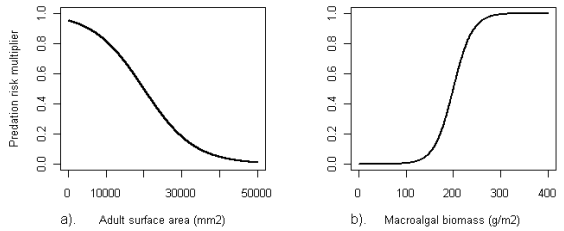

Figure 2: The shape of functions determining the extent to which predation mortality is applied to urchins. a). represents a decline in predation risk with increasing adult surface area due to the spine canopy refuge effect and b). represents the increase in predation risk with increasing macroalgal biomass due to the cultivation effect.

Incorporating an effect of macroalgal biomass required the inclusion of a simple biomass dynamic model for macroalgal growth and urchin grazing such that macroalgal biomass, A at time t is represented by:

$$A_t = A_{t-1} + vA_{t-1}(\frac{1 - A_{t-1}}{C}) - gU_{t-1}A_{t-1} \quad (4)$$

Where C represents the carrying capacity of macroalgal biomass, v the growth rate of macroalgae, and g, the proportion of algal biomass consumed per unit of urchin biomass, U.

Recruitment

Recruitment in the model population was described in two distinct ways; a stock-recruitment function relating to local adult biomass density and an externally driven density-independent level of recruitment. This distinction is important since speculation remains about the extent of larval dispersal in *D. antillarum* and whether larval supply to a local population is produced by that population or comes from source populations elsewhere (Bak 1985; Lessios 2001; Karlson and Levitan 1990).

The stock recruitment curve used to describe density-dependent recruitment was the product of two elements. The first was a depensatory curve representing an increase in fertilization success and larval settlement with increasing spawner biomass density (Fig. 3a). The second was a compensatory curve representing a decrease in larval survival at settlement as spawner biomass density continues to increase (Fig. 3b). Declining larval survival represents conspecific resource competition for suitable settlement space and acts to limit population growth to a carrying capacity.

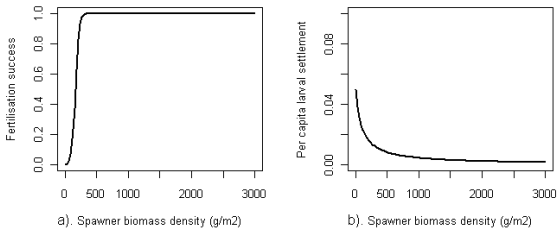

Figure 3: The two functions used to produce the stock-recruit relationship in the model population. A depensatory, logistic curve describing fertilization success (a) and a compensatory Beverton-Holt curve describing resource competition (b).

Biomass density was used in this relationship to allow for differences in gamete production between different sized urchins. The parameters of the curve were set such that they reflected maximum fertilization success beyond a threshold density of approximately one urchin per square meter (Levitan 1991; Levitan and Sewell 1992: Levitan and Peterson 1995) and created a maximum level of recruitment which reflects settlement numbers observed in the field prior to the mass mortality event (Bak, 1985). Figure 4 shows the resulting stock-recruitment curve (a) and the number of recruits produced (b).

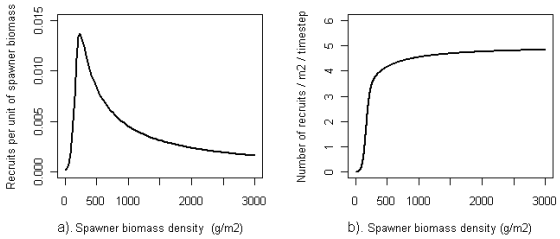

Figure 4: The stock-recruitment curve used to model recruits per unit of spawner biomass density (a) and the resulting level of recruitment per time step with increasing spawner biomass density (b).

Density-independent external larval supply was represented by the addition of a constant number of recruits at each time step.

Results

The *D. antillarum* population can persist in a low and a high abundance state. The low abundance equilibrium is associated with high macroalgal biomass whereas the high abundance equilibrium is associated with low macroalgal biomass. Due to the depensatory effects associated with adult spine canopy and macroalgal cover, a high initial abundance of large juvenile or adult *D. antillarum* is required for the system to switch to the high abundance state. (Fig. 5). Note that there can be a

substantial time lag associated with growth to high abundance equilibrium.

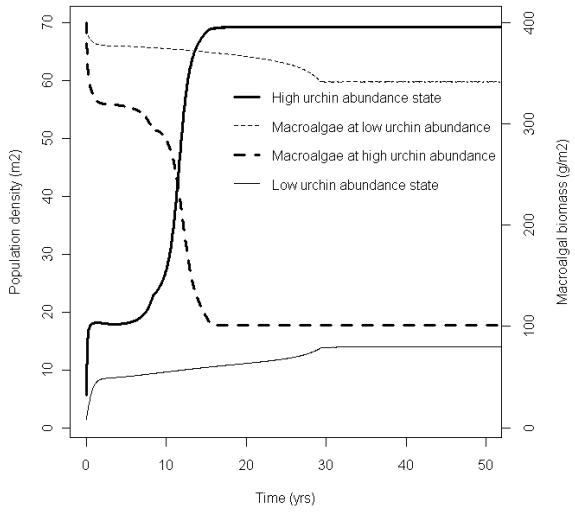

Figure 5: *D. antillarum* abundance and macroalgal biomass trajectories leading to low and high abundance equilibria, following releases of 1.4 and 5.6 medium-sized individuals per square meter. Solid lines represent urchin density, dashed lines represent macroalgal biomass and the thickness of the line denotes high or low abundance state with respect to urchins

We used the model to examine the number of urchins of different sizes required to kick-start rebuilding of a locally extinct population to a viable low or high abundance state, given high or low initial macroalgal biomass (Figure 6). Very high numbers of small urchins are required to establish a viable population, particularly when macroalgae are abundant. Much fewer large urchins would be required and establishment success with large urchins is less sensitive to the abundance of macroalgae.

The same method was used to assess threshold densities under a scenario of density-independent larval supply. The threshold densities for a high abundance state were very similar to those shown in Figure 6, the only significant difference being that there was no extinction threshold and the population would always persist even at low abundance.

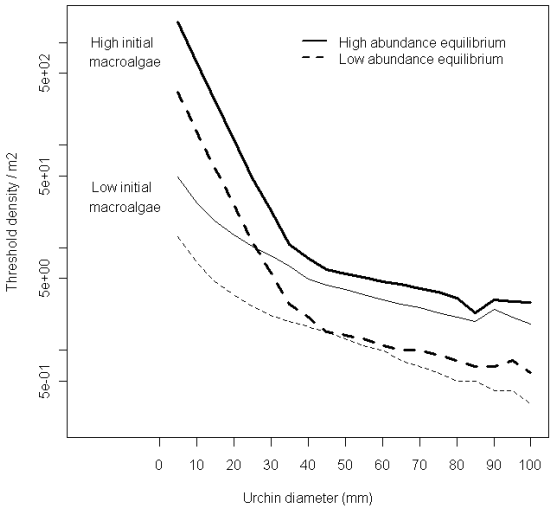

Figure 6: Threshold initial densities of urchins in each size class required to produce a population at low or high population abundance with an Allee effect in fertilization success, a spine canopy refuge and a habitat cultivation effect. Density thresholds are shown on a log scale.

Discussion

This study represents the first attempt to model the population dynamics of *D. antillarum* and gain a quantitative understanding of mechanisms impeding population recovery. The model represents mathematically key ecological processes and allows exploration of their population-level consequences.

The existence of both low and high abundance equilibria associated with high and low macroalgal biomass provides a possible explanation for the observed persistence of population densities much smaller than those seen prior to the mass mortality event of 1983. If, as our study suggests, macroalgal biomass plays a role in *D. antillarum* population dynamics then stable low population abundance may be due to the phase shift in macroalgae observed since the mass mortality event. However, the time lag involved in switching from the low to the high abundance state suggests that some low abundance natural populations may eventually recover

The existence of threshold densities for extinction and the two equilibria provides support for the potential for active rebuilding strategies. If we can aid populations to overcome threshold densities, then positive feedback associated with fertilization success, a spine canopy refuge and habitat cultivation may allow populations to persist and to recover to high abundance states.

As our studies show, even in the presence of sufficient larvae, population growth to high abundance is determined largely by juvenile predation mortality and the availability of predation refuges. The release of hatchery reared larvae alone is

therefore unlikely to prove effective if not coupled with some sort of refuge provision.

Model predictions show that urchin size and macroalgal biomass have significant effects on the thresholds required for population persistence and growth. In all situations, the larger the size of individuals, the lower the threshold densities required. It was also true that threshold densities were always lowest from a starting situation of low macroalgal biomass. These results suggest that adult release or translocation alongside prior macroalgal removal to mimic habitat cultivation may be the best rebuilding strategies. Adult urchins are less susceptible to predation mortality but also act to improve the survival of juveniles through spine canopy refuge and habitat cultivation. However, the large-scale release of urchins of large enough size at high enough density is logistically difficult since few are naturally available for translocation and we are yet to develop aquaculture technology for rearing adult *D. antillarum.* Previous translocation attempts have in fact proved unsuccessful due to low levels of retention and high levels of mortality (Miler et al 2007). A recent study in Curacao however, showed encouraging evidence that the provision of artificial predation refuges could greatly improve translocation success (Dame 2008). This supports the predictions of our model by highlighting the importance of predation mortality and refuge availability. An alternative to artificial refuge provision may be in the artificial removal of macroalgal to mimic the cultivation effect. Removal of macroalgae may free up existing predation refuges whilst simultaneously promoting larval settlement.

We propose that habitat modification in the form of macroalgal removal should be coupled with future attempts at translocation or hatchery release in order to promote survival and recruitment.

It is hoped that this study will promote further investigation into the role of macroalgal cover and habitat structure on larval settlement and juvenile survival in *D. antillarum.* This and future population dynamic models for *D. antillarum* provide an invaluable tool with which to quantify population recovery, direct future empirical work and advise rebuilding strategies.

2) Senior Research Fellow, WorldFish Center, Penang, Malaysia

Abstract. This paper presents preliminary results from a multidisciplinary research project on factors influencing the performance of Marine Managed Areas. This study is unique in that it investigates the impact of the timing of management interactions on a number of performance outcomes, across a global sample of MMAs. Data sources for the study comprise an extensive review of literature, key informant interviews, and household surveys in 24 villages from eight MMA sites in tropical regions. Analysis of household surveys indicate that adequate funds at the beginning, enforcement, shared benefits, community organizations, conflict management mechanism, and external support during implementation, and education and training programs, government support, and legislation today together account for 18% of the variance in the socio/ecological component of MMA performance. Alternative livelihoods, shared benefits, and leadership in the beginning, education and enforcement during implementation, and legislation, conflict management, and accountability today account for 17% of the variance in the empowerment and security component of MMA performance. Finally, the combined effects of community influence and education in the beginning, consultations, leadership and education programs during implementation, and influence, shared benefits, community organizations, and legislation today, account for 20% of the variance in the conflict component of MMA performance.

Key words: Marine Protected Areas, Economics of natural resources.

Introduction

The purpose of this study is to assess the factors related to the social and environmental effects of Marine Managed Areas (MMAs). In particular, it explores the links between socioeconomic, governance, and ecological circumstances, events, or interventions and changes in the human or natural environment of the MMA over time.

Attention to the links between MMA design and implementation processes and their longer-term outcomes has increased in recent years. In June of 2006, the Food and Agriculture Organization of the United Nations convened an expert group to develop recommendations for the use of Marine Protected Areas as a fisheries management tool. The panel, composed of social and environmental scientists from many disciplines, developed numerous recommendations for the effective design and management of MPAs. The panel noted that "the design of MPAs would benefit from more support for effectively designed and conducted studies of MPAs, emphasizing the diversity of situations in which MPAs have been applied, design and implementation processes, monitoring and performance, and ultimately, lessons learned." (FAO 2006)

This study support the goals articulated in the FAO document by investigating the relationships between socioeconomic, governance, and ecological factors and MPA outcomes. As noted by Pomeroy and Mascia in the FAO report, "The four principal elements of MPA design – decision-making arrangements, resource use rules, monitoring and enforcement systems, and conflict resolution mechanisms – directly and indirectly shape human resource use patterns and, ultimately, the biological and social performance of MPAs." (FAO 2006)

Material and Methods

Data sources for the study comprise an extensive review of literature, key informant interviews, and household surveys in 24 villages from eight MMA sites in tropical regions.

Figure 1 is a graphic representation of the analytic framework for this study. The outcomes (effects) of the MMAs are defined as a difference in the levels of MMA performance indicators from a time before the MMA was initiated to today. Socioeconomic, governance, and ecological factors were measured at three time periods – in the early phases of the MMA project, during implementation of the MMA, and today. The curved arrows in the graphic represent relationships between the socioeconomic, governance, and ecological factors that are related to the outcomes of MMAs. The dark, straight arrows represent

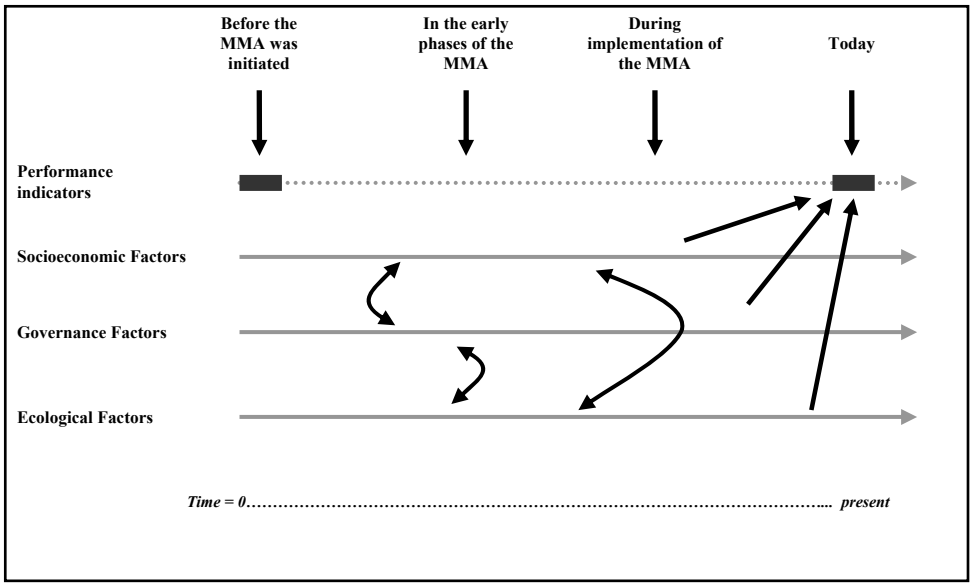

Figure 1: Analytic framework for GME study

relationships between independent variables (socioeconomic, governance, and ecological factors) and dependent variables (the change in performance indicators, or the effects of the MMA).

In order to conduct a quantitative assessment of the relationships between these dependent and independent variables, it was necessary to obtain comparable data from each MMA site. Although these sites were chosen based in part on the availability of secondary data, the data on socioeconomic and governance factors was not directly comparable across sites. Therefore, it was decided to conduct surveys with 40-60 households at each MMA. These surveys utilize the baseline-independent method for impact evaluation developed by Pomeroy et al. (1997) and widely employed by authors involved in coastal management research since that time (for example, Cinner et al. 2005; McClanahan et al. 2006). These household surveys provide comparable data on socioeconomic and governance factors present at each site and their timing, as well as the levels of socioeconomic and governance performance indicators before the MMA project and today. A significant difference in the reported level of a performance indicator is considered an effect of an MMA.

The household surveys were developed following a review of guidelines on the socioeconomic assessment of MMAs and coral reef management (Bunce et al. 2000; Pollnac 1998; Pomeroy et al. 2004). The survey instrument consists of three sections and about 50 questions. The first section contains questions about general household characteristics, respondent demographics, and community characteristics. The first section also asks the respondents whether they consider the MMA a success. The second section asks about the timing of factors that might be important in establishing and managing an MMA. These are our Critical Determining Factors, or CDFs.

The third section asks about respondent perceptions of the level of indicators (before the MMA and today) that could be considered the outcomes or outputs of MMAs. This study uses a visual, self-anchoring, ladder-like scale which allows for making fine ordinal judgments, places minimal demands on informant memory, and can be administered rapidly. Using this technique, the subject is shown a ladder-like diagram with 10 steps. The subject is told that the first step represents the worst possible situation. For example, with respect to coastal resources, the subject might be informed that the first step indicates an area with no fish or other resources, that the water is so foul nothing could live in it. The highest step could be described as rich, clean water, filled with fish and other resources. The subject would then be asked where the situation was before the MMA, and where it is today.

In all cases, local partners were enlisted to lead the implementation of the household surveys. The research team worked on-site with each local project leader to ensure that the survey questions were clear, and that they were appropriate to the communities being surveyed. Samples were drawn from the population of stakeholders in communities surrounding or near to the MMA who are involved with or are knowledgeable about the MMA. These individuals were either identified by the survey enumerators on-site by asking a screening question of randomly selected community members, or pre-

screened by MMA management prior to the research visit.

Results

For the overall sample, there was a statistically significant increase in perceived levels of all 12 of the impact indicators (p<0:01). In particular, there were large positive changes perceived in compliance, and ecological health and biodiversity. The next highest positive change was in livelihoods, with the smallest changes reported for peace and order and crime levels. Changes in the levels of effect indicators were not as pronounced for the subsample of fishers.

Indicator	T2-T1	P
Livelihoods	1.348	<0.01
Food security	.973	<0.01
Resource conflicts	1.054	<0.01
MPA conflicts	.933	<0.01
Participation	1.143	<0.01
Influence	1.233	<0.01
Peace and order	.877	<0.01
Crime	.771	<0.01
Village conflict	.935	<0.01
Compliance	2.247	<0.01
Ecological health	2.294	<0.01
Biodiversity	2.126	<0.01

Table 1: before/after MMA differences in perceptions of performance indicators

The next step was to reduce the number of independent variables for further analysis. Principal component analysis with varimax rotation was used to elucidate patterns of relationships between the degrees of change in the 12 indicators. The scree test was used to determine the number of components, resulting in three components, which account for a total of 62% of the variance in the data set.

	Component		
	1	2	3
Livelihoods	.639	-.065	.470
Food security	.659	-.038	.458
Resource conflicts	.254	.181	.773
MPA conflicts	.131	.244	.806
Participation	.032	.712	.310
Influence	.034	.682	.322
Peace and order	.340	.591	.073
Crime	.213	.686	-.053
Village conflict	.426	.358	.454
Compliance	.620	.384	.165
Ecological health	.794	.232	.109
Biodiversity	.841	.264	.079

Table 2: factor loading for principal component analysis

Items loading highest on the first component are clearly related to both livelihoods and ecology; thus, the component is named ''*Socio/ecological*.'' On the second component items related to participation and peace and order load highly, resulting in identifying the component as indicating ''*Empowerment and security*.'' Finally, items loading highest on the third component are related to various types of conflict in the community; hence, the component is named ''*Conflict*.''

We can then investigate the relative importance of the predictor variables in terms of their individual and combined ability to account for variance in the three indicator components. This can be accomplished with regression analyses, and most efficiently with stepwise regression analysis. The results of these analyses for the three components can be found in Table 3.

Table 3: regression coefficients

The results in Table 3(A) indicate that adequate funds at the beginning, enforcement, shared benefits, community organizations, conflict management mechanism, and external support during imple mentation, and education and training programs, government support, and legislation today together account for 18% of the variance in the Socio/ecological component score.

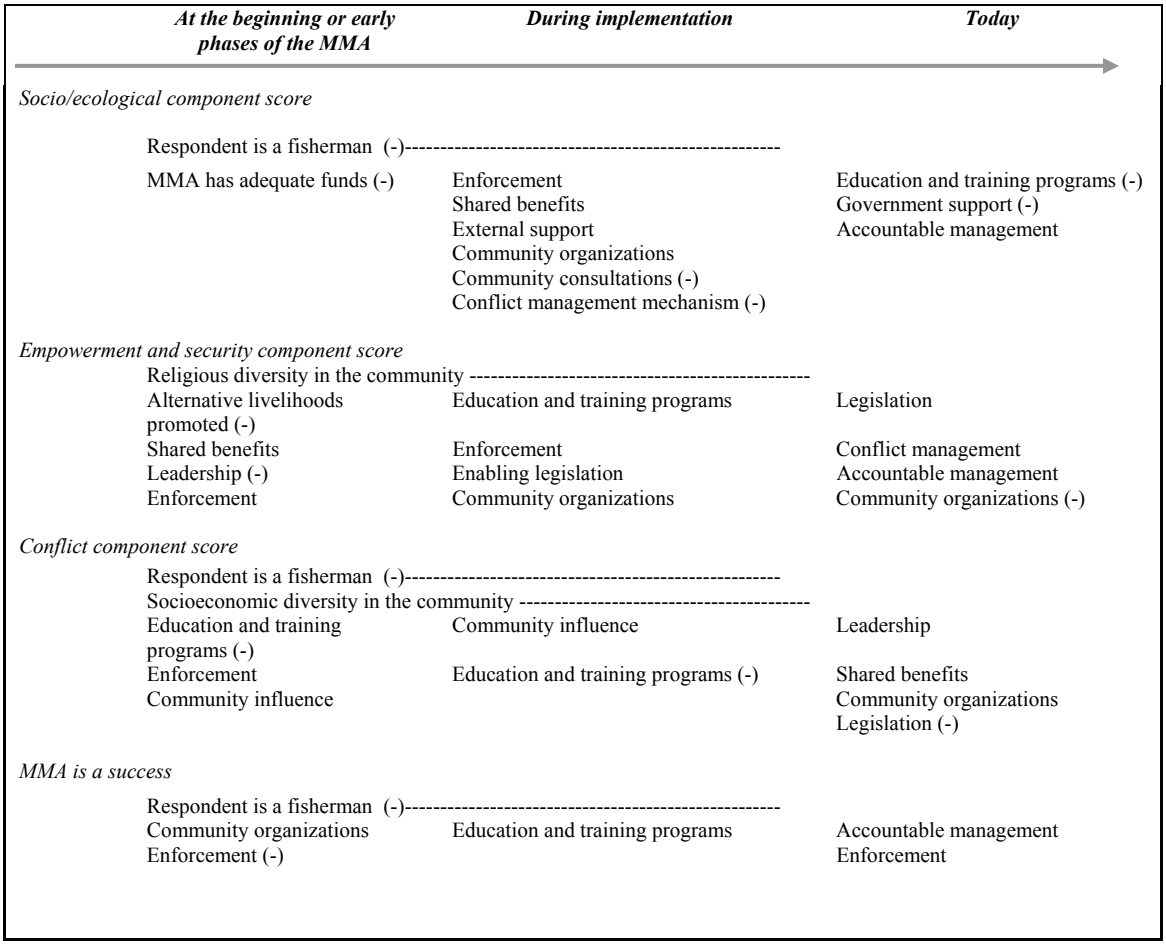

Figure 2: timeline representation of significant regressors

Likewise in Table 3(B), alternative livelihoods, shared benefits, and leadership in the beginning, education and enforcement during implementation, and legislation, conflict management, and accountability today account for 17% of the variance in the Empowerment and security component score. Finally in Table 3(C), the combined effects of community influence and education in the beginning, consultations, leadership and education programs during implementation, and influence, shared benefits, community organizations, and legislation today, account for 20% of the variance in the Conflict component score. Figure 2 is a timeline-type representation of these regression results.

Discussion

The most striking result of the component regressions is that some of the coefficients are negative, contrary to expectations. Recall that these are supposed to be critical *success* factors; therefore all coefficients would be expected to be positive. Thinking about the implications of measuring perceptions can help to make sense of these counterintuitive findings. For example, there may be some psychology at play in which respondents feel a sense of "bonding together in a difficult situation" that would explain why the coefficient on *adequate funds* is negative. Similarly, both *alternative livelihoods* and *leadership* at the beginnings are negatively related to the empowerment and security component score. Recall that the empowerment and security component is loaded most highly with perceptions of changes in influence and participation. It might be the case that if a strong leader comes in to a community with new ideas about changing traditional ways of life, that situation could be alienating and disempowering for some members of the community.

In general, the variables with negative coefficients are associated with situations that may be generated from outside the community itself – for example, strong leadership, legislation, education and training programs associated with the MMA, government support.

It is also noteworthy that some of the coefficients are positive for one component but negative for another. Education and training programs, for instance, have a positive effect on the *Empowerment and security*

component score but a negative effect on the other two components. Strong leadership has a negative effect on the *Empowerment and security* component score but a positive effect on the *Conflict* score. Investigating the robustness of this finding will be a fruitful area for further research.

This paper reports results from the first phase of an ongoing research project. Further steps will involve integrating quantitative ecological data from study sites into a comprehensive analysis. The authors welcome comments from readers to improve future versions of this report.

Acknowledgements

This research was made possible with the financial support of Conservation International's Marine Management Area Science program. We would like to express our sincere gratitude to the committed teams of local researchers who made this project happen, especially Haji Mahingika, Narriman Jiddawi, and Ali Abdullah in Tanzania, Michael Pido in the Philippines, Kim Ahn in Vietnam, and Nadia Sonia Cazaubon in Saint Lucia.

Towards a close integration of social and natural sciences

A. Coghlan[1]

1) James Cook University, School of Business, Cairns PO Box 6811, Qld 4870, Australia

Abstract. Interdisciplinary teams are now commonplace in natural resource research centers. The evolution from pure biologists to a systems approach with ecologists and later on, social scientists and geographers reflects our understanding that no natural environment is exempt from human impacts; to protect the natural environment we must incorporate the human dimensions within the environment. Whilst conceding that interdisciplinary research is vital to the conservation of natural resources, I review our state of knowledge on interdisciplinary research and identify several barriers to successful integration. To address these, it is necessary to first articulate and understand these barriers. Only then can they be identified as they arise between researchers and successfully overcome in order to achieve sustainable natural resource management. This paper identifies four major barriers that hinder efforts at successful integration of social and natural science. These are (i) differences in epistemology, (ii) the place and hierarchy of each science within the wider community, (iii) researcher time constraints and (iv) publication pressures. The paper also provides a list of recommendations to overcome these issues in order to guide researchers through the challenges of producing integrated, quality, outcome driven research that serve both the community and the natural environment.

Key words: Interdisciplinary research natural social science

Introduction

A cursory glance at some of the major natural resource research centres around the globe reveal a trend towards interdisciplinary research teams. One example of this trend include the Australian Centre of Excellence for Coral Reef studies, which employs ecologists, biologists, geneticists, sociologists, economists and anthropologists.

The evolution of teams based in one discipline, e.g. biologists, to a system approach with ecologists and later the addition of social scientists and geographers reflect our understanding of the complexity of natural environment and its interconnectedness with human society and its impacts; we now realize that we must examine the system as a whole if we wish to protect it. For example, a relatively simple but pertinent question such as "How can the harmful environmental impacts of human activities be reduced?" can draw on the disciplines of demography, ecology economics, engineering, sociology, psychology, anthropology, political science, law and ethics in order to reach a satisfactory answer (Daily and Ehrlich 1999).

In addition, there is a recognition that, in order to successfully protect a natural resource such as coral reefs, there must be local support for the projects, and some incentive to preserve and manage the resource. Often in cases where no social scientist is immediately available, the responsibility falls to the natural scientist who has been working near or alongside the local community for many years to develop the incentive to preserve and manage the resource. However, as highlighted by the review of issues in interdisciplinary research that follows, an ad hoc, *cross*-disciplinary approach may not always be successful or achieve the desired outcomes; indeed authors such as Lele and Norgaard (2005) suggest that "charged with providing policy recommendations, natural scientists have to make judgments about how society works. They do not have adequate training to do this, but they are perhaps emboldened to do so by their positions and are likely to adopt simplistic models of social dynamics".

In this paper, I look first at the growing need for interdisciplinary research teams in natural resource management and environmental conservation. Next I draw on the literature, as well as personal experience, to identify and articulate some of the issues that such interdisciplinary research appears to face. Finally, and again based on existing literature in the area, some of the recommendations for overcoming these issues are discussed.

Literature review

When it comes to incorporating the social sciences into natural resource management, both natural scientists and social scientists may find themselves frustrated. Campbell recounts her experiences working with natural scientists at a turtle hatchery: "I was once asked to conduct research that would "show" that tourism was more valuable than an extractive-use project. Biologists may see results that do not see a desired conservation outcome as a

betrayal, both personally and professionally" (Campbell 2005). One reason for this, according to Campbell, is that natural scientists "may have unconscious or assumed expectations about what results of socio-economic studies will show", and which do not always reflect the research paradigms or priorities of the social sciences.

Indeed, some authors suggest that several misunderstandings may be at work here. First, a more palatable form of social science may be co-opted into a primarily natural science research team. In the words of Redclift (1998) "There is considerable evidence that some kinds of research in the social science can be fashioned to meet the demands of the natural sciences, e.g. demographic analyses can provide scenarios of food availability, surpluses, and resource scarcities. But is this social science? Is it rather what natural scientists think that social scientists are doing?" As a more extreme example we find the following "In my experience, natural scientists turn to social scientists to better package or market their eco/bio principles to the general public. True collaboration suggests mutual recognition of the distinct theory and methods that respective disciplines can bring to complex problems" (Fox et al. 2006).

Conversely, however, it has been argued that social scientists must also be able to "demonstrate that conservation-relevant social science is legitimate, worthy of pursuit and capable of answering questions of profound theoretical significance" (Mascia et al. 2003). Clearly there is some feeling amongst the natural scientists that social science has in the past failed to provide the conservation outcomes required for adequate protection of a natural resource, and a certain level of frustration felt by social scientists working within conservation-oriented research teams.

Aims and Objectives

The aims of this paper are to:

1. To articulate some of the issues that face interdisciplinary teams
2. To help think about them and identify them as they arise
3. To make some recommendations for overcoming them

Material and Methods

The principle methodology for this paper is a review of the literature on interdisciplinary research, with a particular focus on those issues that arise in mixed social and natural science teams. The review is set within the author's own experience as a graduate in marine and environmental sciences, a doctoral degree in tourism, and a postdoctoral position in the School of Business, managing a research project on sustainable use of marine resources within a tourism context.

Results

Based on some of the ideas presented above, as well as a more complete review of the existing literature, it would appear that there are four main issues that may lead to communication breakdowns in interdisciplinary teams. These are (i) differences in epistemology, (ii) the place and hierarchy of each science within the wider community, (iii) researcher time constraints and (iv) publication pressures.

(i) Differences in Epistemology:

Differences in epistemology is arguably the biggest area of potential conflict between social and natural scientists. (Lele and Norgaard 2005). It can be suggested that natural scientists believe in an absolute truth, which should be reached through a reductionist, positivist approach to reach general consensus, whilst social scientists may employ far more interpretive techniques that encourage debate and move away from consensus, admitting the existence of competing controversial universalities or distinct epistemic communities (Redclift 1998).

A range of other related issues also appear in the literature. For instance, language issues may arise, as differences between a clearly technical language and a science built upon more common language may lead to misunderstandings. In particular social scientists who often use common language in their research complain that the uninitiated reader, may mistakenly conclude that he understands what is being said (Pearce 2008, pers. comm.; Wear 1999). An example from personal experience is the confusion between the terms tourists and holiday-makers. In these cases, interdisciplinary research requires a clearer description of framing theory and methodology, and some insights into constitutive metaphors in order to build a common language that may usefully serve both groups of researchers (Wear 1999).

A second sub-issue resolves around the sensitive topic of values. This issue arises at all stages – choice of questions, theoretical positions, variables chosen, styles of research. And whilst natural scientists like to think that they are value-neutral, e.g. through the use of the passive tense in reports, social scientists recognize the importance of the context of all research (Lele and Norgard 2005) allowing subjectivity to become part of the research. Moreover, Campbell (2005) points out that advocacy issues can be strong in conservation biology, sometimes to the detriment of science. The goal of conservation biologists is to preserve biodiversity. There is often therefore a value placed on social science that is able to achieve this conservation goal more effectively through

deliverables. Campbell suggests however, that issues of advocacy will influence human subjects through their perceptions of the overall research team and project and not just by the social scientists with whom their interact. This will have detrimental effects on the quality and validity of the social science.

(ii) The place of science in society:
Another sensitive issue that is identified in the literature is that of the place of science in society and associated issues of funding (Roughley 2005). A form of hierarchy of intellectual rigor appears to exist in the sciences from the so-called "hard" sciences such as physics and chemistry through to "softer" sciences such as ecology and psychology, leading finally to anthropology and sociology. This hierarchy of worth, and the funding discrepancies associated with it has been accused of creating arrogance or defensiveness within disciplines, and forming a barrier to successful interdisciplinary research. Some authors therefore argue for personal characteristics of interdisciplinary researchers to be carefully considered, and point to the need for trust, patience, responsibility and honesty (Naiman 1999).

This may also help to overcome apparent issues of power imbalances, whereby research leaders are often based in the natural sciences and the natural scientists, by the nature of research methods, may outnumber the social scientists. The interpersonal skills of the research leader will therefore also play an important role in creating good interdisciplinary science within large teams. He or she will need to ensure that everyone shares the same general vision, but have specific parts of the overall project so that they have ownership. This may require the commitment of senior people who have little to risk professionally and are anxious to involve bright junior people in their efforts. Furthermore, whilst there is often only one social scientist in the team, this person will be required to represent a broad suite of social science concerns and represent the team in a social context, e.g. educate local people or fix socio-economic problems. Both of these roles are demanding and can be exhausting, and again, require good interpersonal skills and a strong commitment to the project.

(iii) Issues of time:
When talking about interdisciplinary research, it has been suggested that mutual understanding and cooperation build slowly (Daily and Ehrlich 1999). Social interaction and long-term association that allow friendships to develop create stronger interdisciplinary teams. Furthermore, it takes time to develop common language and familiarise oneself with other disciplines, as well as build the research program around several disciplines so that it may be truly inclusive, empowering and truly reflect the issues at hand (Naiman 1999). On the other hand, conservation has a certain level of urgency associated with it. It may be therefore that much of social science research and methodology are a luxury that conservation practioners cannot afford (Brosius 2006).

Another issue that is related to time constraints is the issue of good science: the commitment of time and energy into understanding other disciplines invariably detracts from the time and commitment put into maximising one's own mastery of a single discipline. The result is a perception that interdisciplinary scientists are less competent or accomplished, and that interdisciplinary science is less exacting (Fox et al. 2006).

(iv) Publishing Issues
A final major issue that has been noted in the literature comes with the publication process for researchers. Pressures to publish in high ranking academic journal may limit incentives to publish in the newer interdisciplinary journals, or in journals that may not lead to high citation rates. Furthermore, reviewing processes might be more difficult as interdisciplinary articles require more time and effort from editors and reviewers. Review processes for interdisciplinary journal are also felt to be biased towards natural scientists, and reviewers are often interested in and familiar with the issues addressed but unfamiliar with theories and methods. According to Campbell (2005) this does not stop reviewers from suggesting related revisions, usually inappropriately. It is suggested that there is a need to expand list of social scientists on editorial boards and use these more fully.

Discussion
Whilst this review does not provide a comprehensive list of all issues facing indisciplinary research teams, it had highlighted some of the key issues. By articulating some of the more commonly cited issues that arise in interdisciplinary research, it is hoped that researchers in this situation will be able to recognize and circumvent barriers as they arise. Some recommendations highlighted in the literature, particularly in Naiman's (1999) and Mascia *et al.*'s (2003) papers, include the following:

- Make a conscious commitment to cooperate, and visualise and acknowledge the personal and professional sacrifices as well as the rewards
- Cooperate with colleagues who have a similar level of commitment to team research. Team research is freely sharing ideas, a commitment to excellence, being honest and having an arena of mutual respect in which to work

- Choose people that are willing to assume and share leadership and responsibility.
- Take the time to educate new team members and to ensure their ownership of a significant aspect of the project. Build confidence as well as ownership
- Find ways to encourage continuous communication of new ideas, even though one may not always agree, do validate the person as well as his/her willingness to share
- Never forget that we are all individuals with our own strengths and weaknesses. Value everyone in the group, not just those with the best work habits or ideas.
- Learn how to continue learning in an ever changing world, practice tact and patience; demonstrate respect.
- Encourage social scientists to make a greater effort to initiate and obtain funding for their own environmental management or conservation projects, to which they could include natural scientists.
- Hire social scientists for leadership positions and provide them with the mandate to build social science into organisational decision-making
- Enlist social scientists to develop and manage "rapid social assessment" programs, which would provide decision-makers with a rough sketch of critical social information at potential conservation sites through short-term but intensive inquiry.
- Document and share success stories that illustrate the value of social scientific information to "on the ground" conservation results. Such success stories not only foster organisational learning, internal support and conservation success, but also justify donor and organisational investment in the social sciences.

By adopting some or all of the recommendations outlined above, it may be possible to achieve a greater integration of natural and social sciences and achieve significant progress in interdisciplinary research. In conclusion, the greater integration of social and natural science may adopt a more outcome driven approach that creates good, creative interdisciplinary research, in turn allowing communities to adapt to rapidly changing natural environments. Finally, more dialogue between social and natural scientist is encouraged through such media as peer-review publications (examples include the Journal of Environmental Management, Natural Resources Journal and Society and Natural Resources) and conference presentations. The emerging interdisciplinary teams can and should add new perspectives to each science and allow them to learn from each other, particularly, in the words of Lele and Norgaard (2005), once each side acknowledges what the other does not know.

The political aspects of resilience

Michael Fabinyi

Resource Management in Asia-Pacific Program, The Australian National University, ACT, Australia.

Abstract. This study investigates the political aspects of resilience in social-ecological systems. Based on long-term anthropological fieldwork in the Calamianes Islands, Philippines, the study focuses on the diverse and contested human interests that make up social-ecological systems. In the Calamianes, what promotes the interests of one group of people may impact negatively for another group of people, or the ecosystem in which they live. Fishers, for example, have struggled greatly to preserve their patterns of marine resource use, and to oppose various forms of regulation that have been introduced. Following Armitage and Johnson (2006), this study has found that deciding 'for what and for whom are we trying to promote resilience?' becomes a critical question. Answering such a question will require decisions that will favour certain elements or resource users within any social-ecological system, and disadvantage others. The study concludes therefore that such political aspects of resilience thinking require greater attention, and that more attention could be paid to negotiations over tradeoffs among various stakeholders, if the resilience concept is to be more widely accepted in policy and management arenas.

Key Words: resilience, social-ecological systems, politics, anthropology, Philippines

Introduction

This paper emphasises how greater attention could be paid to the political nature of resilience, and of policies designed to promote resilience. Building on the notion that social-ecological systems are made up of diverse and contested human interests, the paper shows how any attempt to promote resilience for the overall social-ecological system will have differentiated impacts and effects among the diverse elements within it. The paper will show how policies designed to improve social-ecological resilience were transformed, and ultimately rejected, by fishing communities concerned with resisting these policies. Here, there is a significant gap between the particular social and economic interests of fishers, and the resilience of the broader social-ecological system. The paper suggests that resilience must therefore be understood within its political context, and that we need to pay more attention to the need for negotiations over tradeoffs among various stakeholders.

Methods

The paper takes an anthropological perspective to examine the issues surrounding the political aspects of resilience and social-ecological systems. Research was conducted for twelve months between September 2005 and January 2007 in the Calamianes Islands. The author was based in two locations during this period: Esperanza, a small coastal community within Coron municipality, and Coron town, the capital of Coron municipality and the largest town in the Calamianes. Coron municipality was chosen to study the political aspects of marine resource management because of the high importance of commercial and small-scale fishing, and the high number of marine resource regulations implemented at the time of fieldwork. Esperanza has a particularly high population of fishers, and several of the MPAs that are discussed in the paper were located in fishing grounds used by fishers from Esperanza. Specific methods adopted for the study included observation at meetings, and numerous formal and informal interviews with a variety of different stakeholders. These included dive operators and divers, fishers of all ages and types, government officials, and non-government organization workers. Interviews with fishers were conducted in Tagalog. In addition to the in-depth data gathered from Coron and Esperanza, the author frequently visited and interviewed residents at other locations of the Calamianes.

Diverse and contested human interests

Scholars in resilience theory have typically tended to reduce the differences between social and ecological systems. Berkes et al. (2003), for example, state that 'the delineation between social and natural systems is artificial and arbitrary'. Social science scholars, however, have tended to emphasise the distinctiveness of human systems because of the vital presence of human agency. Social scientists have long affirmed that human relations with the environment cannot be reduced to energy flows; they contain value and agency (Burnham and

Ellen 1979). Because of the complexity of human agency, this means that social systems contain diverse and contested human interests. It follows that resilience has to take account of such contested interests if it is to be practically applied. As Johnson and Armitage (2006) point out, '[f]or resilience to be useful in assessing social institutions and in marking roads to sustainability and social justice, it has to be situated in the context of complex, contested and changing human interests, and the uncertainty of the outcomes of human interactions'.

The Calamianes Islands can be seen as an example of a social-ecological system that contains diverse and contested human interests with regard to the management of marine resources. The main livelihood for the region is a variety of fisheries, both small-scale and commercial. While several fisheries have boomed and busted since the 1970s, the live fish for food trade is currently dominant; an estimate of the value of the trade in the Calamianes for 2002 was about US$5.3 million (Pomeroy et al. 2005). This fishery has been extremely profitable for local traders and fishers, but has also been highly ecologically destructive, characterised by overfishing and the common use of sodium cyanide (Fabinyi 2007). Stakeholders from the fishing industry have generally attempted to preserve the status quo, with minimal or no regulation of their activities.

Conservationist organisations have been promoting the development of marine protected areas to work with dive tourism, and regulations designed to reform the live fish trade, which included a lengthy closed season. Much government planning and the everyday lives of residents in the broader region can be characterised by contestation over how best to access, exploit and manage these marine resources (Eder and Fernandez 1996).

Socio-political interests vs. social-ecological resilience

While not explicitly framed in terms of resilience theory, both sets of environmental reforms were attempts to promote social-ecological resilience by reducing both the long-term poverty of the coastal communities of the Calamianes, and degradation of the marine environment. The policy brief behind the development of the live fish regulations, for example, stated that '[t]he policy goal is for a sustainable fishing industry in Palawan Province that ensures viable fish stocks, ecosystems and livelihoods for present and future generations' (Pomeroy et al. 2005). Similarly, marine protected areas have been cited as a means of promoting resilience. In the Calamianes, their development was aimed at both maintaining the ecological integrity of particular marine ecosystems, and at livelihoods through the development of tourism and by increasing the overall level of fish stocks.

MPAs

The ways local fishers understood and responded to many of these MPAs was extremely significant in determining their ultimate outcomes (Fabinyi 2008). Importantly, fishers placed their fishing practices within a social and political context. Small-scale fishers generally represented their patterns of fishing as possessing two key features: it was harmless to the environment, and it was closely tied to poverty. In contrast, tourists and tourist businesses were frequently objects of resentment by fishers, the latter seen as undeservingly profiting from the beautiful reefs of the Calamianes. From this perspective, any regulations to try and reduce problems of environmental degradation should not impact on the small time fishers, who could not afford it. They felt that any regulation that interfered with the activities of small-scale fishers, such as MPAs, would have to be accompanied by financial benefits of tourism. These perceptions meant that some [particularly younger] fishers were sometimes opposed to the creation of MPAs if they were not seen as benefiting local communities, and indeed felt justified in still fishing within them. Fishers would only tend to support MPAs if they did not impact significantly on their fishing practices, focusing instead on taxing tourists. Essentially, the perspective of many local fishers was that MPAs which interfered with existing fishing activities were to be opposed, unless they gave significant benefits in terms of tourism money.

The planning processes for many of these MPAs illustrated this perspective of local fishers clearly. What was notable was the ways in which coastal people refused to allow the MPA to have any impact on their particular patterns of marine resource use. During the planning meetings for example, the core or 'no-take' zones were changed from the original locations drawn up by the marine scientists in the conservation projects to account for the presence of several fish traps owned by local residents. And, in the buffer zones of the MPAs, residents ensured that their fishing practices would be allowed, while actively pushing for the fishing practices of neighbouring communities to be disallowed. For all of the fishers, the MPA had no ecological focus, but was viewed as something to support the community; something that was solely about assisting and protecting their livelihoods.

Another key aspect of this planning process of the MPAs could be seen in the desire among fishers to obtain greater benefits out of the tourism industry in the form of user fees, which

were demanded by participants as an essential component of the MPA. For many coastal residents in the Calamianes, the socio-economic differences between foreign tourists and themselves were stark and inescapable. Foreign tourists were typical of the 'rich foreigner'. Their very presence in a place like the Calamianes, pursuing nothing but leisure activities like SCUBA diving, was proof to locals that they had incredible amounts of money to burn. Versions of refrains such as 'You foreigners throw money away like it is rubbish' were commonly stated assumptions among local fishers. In contrast, the Philippines was understood to be the most poverty-stricken place on Earth.

The development of MPAs in the Calamianes can be seen as stimulating a sense of territoriality over the protected areas. In effect, they produced an artificial form of marine tenure or ownership among coastal communities. The rationale behind fishers' support for these MPAs had less to do with conservation or even fisheries management, but more to do with an expression of political, livelihood claims. Fishers viewed MPAs as a way in which they could address some of the massive inequalities between themselves and those involved in the tourism sector. The claims of fishers about MPAs were based not on a logic of environmental management, rather on a belief that their poverty ought to be the focus of any external environmental intervention. For fishers, no purely technical, scientific management of MPAs would be fair or legitimate without taking into account their claims. As it turned out, these claims favoured the development of particular types of MPAs that had minimal restrictions on local fishers, were loosely enforced when it came to fishers, and involved user fees for tourists.

The status of many of the MPAs in the Calamianes could be seen as somewhat ambiguous. Many were being created, but most of them were marked by serious shortcomings and limitations. Core zones were often minimised as much as possible and seen as a concession to conservationists, buffer zones were adapted to include the fishing techniques and gears of local fishers, and enforcement was rarely effective when it was conducted by locals. Whether the MPAs produce the increase in fish stocks as desired by the conservationists (and the fishers) remains very unclear because of these sorts of shortcomings. So, from this perspective, the proliferation of MPAs is not so much a victory for wise fisheries management or the promotion of social-ecological resilience, but more a way in which local fishers and some sympathetic local government officials were able to successfully advance their interests.

Live Fish Trade Regulations

The second piece of environmental management that coastal communities responded to was the implementation of a series of regulations designed to reform the live fish trade. These regulations were approved in March 2006 at the provincial level, but the political system of the Philippines requires that provincial laws have to be approved by municipal laws before they are actually implemented in those specific municipalities. So, for most of 2006, the provincial council and the various municipal councils that supported live fishing were locked in a stalemate arguing about the new live fish regulations.

At different points through 2006, the provincial government threatened the municipalities involved in live reef fishing with a moratorium on the renewal of all live reef fishing accreditations if these regulations were not adopted. Finally, in December, after a whole year had passed without the municipal governments creating specific municipal ordinances, the provincial Bureau of Fisheries and Aquatic Resources enforced a ban on all live fish exports from Palawan. Immediately after this, furious lobbying and negotiations occurred. Fishers went to the traders that supported and financed their fishing activities, asking for help. They argued that the imposition of the regulations was extremely unfair; that if there were any problems in the live fish trade it was, according to them, only because of a small number of fishers who used cyanide. The rest of the fishers who used legal methods should not be punished for the actions of a few. They argued that by imposing a closed season and creating MPAs in the best fishing grounds, this would send them back to the poverty-stricken lives they had lived before the introduction of the live fish trade in the Calamianes. In particular, fishers emphasised that the live fish trade was the only significant commercial industry in the Calamianes, and no alternative livelihoods existed that could even come close to the live fish trade in terms of financial benefits. Many people would go hungry, the fishers argued, and other community members also protested at the regulations, claiming businesses such as general stores would also suffer. Gaining national headlines in the newspapers, more than 500 fishers eventually trooped to the capital of the province to protest at the creation of the regulations.

It seemed for a while that the provincial council was not going to back down, and that the moratorium would hold. Eventually however, they gave in to intense pressure by their local constituents. The ban was overturned at the New Year, and shipments were allowed to go through again. Another year and a bit on in 2008, and the

live fish trade continues in Coron with little regulation.

Adger has defined social resilience as 'the ability of communities to withstand external shocks to their social infrastructure' (2000: 361). In the terms of this and other definitions the overall social resilience of fishers was probably quite low, given their high dependence on fishing and their lack of economic flexibility. However, suddenly taking a large part of this livelihood away through powerful regulations would have certainly increased their vulnerability in the short-term at least, no matter how immensely important the ecological justifications were. In both of these cases, fishers were acting against what they perceived as a clear potential shock to their social and economic infrastructures. In a region with few available alternative livelihoods, the introduction of MPAs and a closed season for the live fish trade would have had a significant economic impact. It was therefore in their interests to oppose the live fish regulations and to influence the implementation of MPAs the way they did.

Discussion

In this context then, a contradiction can be observed between the resilience of the overall social-ecological system, and the interests of fishers and local government. Supported by the municipal government, fishers were able to promote their interests by manipulating the design of MPAs so that their social and economic benefits remained, and by rejecting the live fish trade regulations that would have heavily disrupted their most important economic livelihood. In doing so, such outcomes compromised the ecological resilience of the social-ecological system. This basic contradiction leads to a fundamentally important question about social-ecological resilience — how is it possible to promote social-ecological resilience when any social-ecological system is composed of diverse and contested human interests? Or as Armitage and Johnson ask, '[h]ow do we balance these divergent interests and the interest of ecological sustainability to define the ideal resilient system?' (2006).

Many analysts have argued strongly for the principles of 'good governance', as articulated through the themes of adaptive co-management, polycentric governance, interactive governance and other related terms (Armitage 2008). Lebel et al. (2006), for example, hypothesise that the existence of participation, polycentric and multilayered institutions, and accountable and just authorities can be associated with an increase in resilience for social-ecological systems.

But while in many cases good governance may clearly be associated with resilient social-ecological systems, in many cases it is not, as Lebel et al. also acknowledge (2006). As Armitage (2008) argues, governance attributes such as those described by Lebel et al. (2006) are 'productive and important, but they are circumscribed by context, and… provide only partial direction for governance innovation. They represent a set of "prescribed" and normative governance values or principles'. During the introduction of the environmental regulations in the Calamianes, for example, attention was paid to various principles of good governance outlined earlier. Indeed, it was the very existence of strong participation by the fishers in the design of the MPAs that led to their ecological compromise. In both instances, governments ultimately were accountable to their constituents and responded to what the majority of the stakeholders wished for, which were MPAs that fulfilled short-term social and economic objectives but had little ecological function, and the rejection of regulations for the live fish trade that would have been beneficial ecologically, but undoubtedly socially and economically damaging in the short-term. This can be seen as an example of governance that is good when understood from the perspective of the interests of fishers and the municipal government, but clearly damaging when viewed from the long-term perspective of the social-ecological system.

Some have lauded the potential of good governance to provide a situation which will be mutually beneficial to all stakeholders. In contrast, perhaps what we need to be more aware of is the inevitability of 'hard choices' in marine resource management (Bailey and Jentoft 1990). Any decisions taken at the scale of the social-ecological system are going to privilege some elements within this system, and alienate others. As in the case of the Calamianes, what may promote resilience for the system as a whole may not always be in the direct interests of particular groups within that system. Therefore, resilience, and activities undertaken to promote resilience at the scale of the social-ecological system, must be seen as a political concept. Resilience, like any other concept for ecological management, including those that emphasise good governance, cannot remove the need for political decisions and negotiations among diverse stakeholders to be made in particular local contexts.

Similarly, practitioners in the field of integrated conservation and development projects have recently emphasized the need for greater attention to and understanding of the goals and interests of all the stakeholders around protected areas, noting that win-win solutions are usually unachievable: 'Once these different interests are identified, clarified, and understood,' they argue,

'the opportunities for negotiation and tradeoffs can be explored' (Wells et al. 2004).

This paper has argued that we need to place greater emphasis on such political aspects of resilience if it is to succeed as a viable and practical management or policy concept. While resilience may be a useful metaphor to understand features of social-ecological systems, focusing on issues at this level of abstraction actually obscures somewhat the diverse social and political relations that actually make up these social-ecological systems, and how resilience affects and is affected by these relations in different ways.

Acknowledgements
This research was conducted while I was a Visiting Research Associate at the Institute of Philippine Culture, Ateneo de Manila University, and was funded by an Australian Postgraduate Award at the Australian National University. I thank both institutions for their support. Thanks to Colin Filer, Simon Foale and an anonymous reviewer for helpful comments on earlier versions of the paper, and thanks to all the residents of the Calamianes who assisted in the research.

New eco-development initiatives involving local people in the conservation of Mahatma Gandhi Marine National Park, Wandoor (India)

A. Saxena[1] & M. Saxena[2]

[1] Women Scientist, Port Blair, A & [2] Managing Director, Andaman & Nicobar Islands Forests & Plantation Development Corporation Limited, Van Vikas Bhawan, Haddo, Port Blair, Andaman & Nicobar Islands (India) Email: dr_aloksaxena@rediffmail.com
N Islands (India) Email: dr.manisaxena@gmail.com

Abstract. Mahatma Gandhi Marine National Park situated at Wandoor about 29 km from Port Blair is among the first three Marine National Parks in India. Established in 1983 with the objective of conserving the unique marine diversity and the coral reefs, it also comprises 15 uninhabited islands. There are 6 villages in the adjoining area with a population of about 4157. The main occupation is fishing. No fishing is allowed within the Marine National Park but routes are demarcated for providing safe passage to local fishermen. MGMNP is an important eco-tourist site because of its unique marine biodiversity. In order to involve the local people in the conservation efforts, the Park authorities initiated action at a small level in 2003-04. The tsunami of 2004 affected not only tourism but also the efforts of Park authorities in people's participation. Increased tourist inflow in the last two years led the park authorities to revive their eco-development initiatives. New initiatives are being taken for providing livelihood means to locals and involving them in the conservation efforts.

Key Words: Eco-development, tourism, fishing routes, livelihood options, Peoples' participation

Introduction

Mahatma Gandhi Marine National Park (MGMNP) was established in 1983 under the Wildlife (Protection) Act, 1972, with a view to protect and conserve the rich marine life found in this area. This was the first Protected Area notified in this Union Territory and also among the first three Marine Protected Areas of India. It is situated around 29 km from Port Blair, the Capital town of the Andaman & Nicobar Islands. The otal area of MGMNP is 281.50 km^2 which includes 220.5 km^2 of territorial water and 61 km^2 of land area of 15 Islands located within the boundary of the National Park. All the Islands within MGMNP are uninhabited. Only two Islands namely Jollybuoy and Redskin are open for tourism, but no night halt is allowed. The Park is completely free from all rights. It is managed by the Department of Environment & Forests, Andaman & Nicobar Administration.

Biodiversity Status

The Park is known for its rich biodiversity-both plant and animals. There are 279 species of plants. Most of the islands have tropical evergreen forests and mangroves on the fringes. The tree species include *Dipterocarpus, Terminalia, Pterocarpus, Diospyrus marmorata, Artocarpus chaplasha* etc. Littoral species are dominated by *Manilkara littoralis* and important mangrove species are *Rhizophora, Bruguiera, Avicennia officinalis, Ceriops tagal.*

The terrestrial fauna include Andaman wild pig, spotted deer, water monitor lizard and a variety of snakes including sea snakes. The birds include Andaman teal, white-bellied sea eagle, parakeets, sea herons among many others.

The Park is rich in marine biodiversity. More than 280 species of fish, 57 species of mollusc, 52 species of echinoderms, 122 species of corals belonging to 54 genera, salt water crocodiles, four species of sea turtle, dolphin, dugong, a variety of sea weeds and sea grasses are reported to occur (Kulkarni et al., 2000, 2004).

Socio-economic status of communities living around

There are no inhabitants within the boundary of MGMNP. However, six villages adjoin the boundary of the Marine National Park. Population figures of these villages as per 2001 census are given in Table 1. Occupational pattern of the villagers is depicted in Figure 1 (Kulkarni et al., 2004). The data shown in Figure 1 is pre-tsunami data (i.e., before 2004). There has been a significant

Table 1: Population of villages adjoining villages

Sl. No.	Name of village	Population
1.	Wandoor	1511
2	Hashmatabad	616
3	Guptawara	716
4	Manglutan	575
5	Manjeri	585
6	Rutland	154

change in the occupational pattern after the area was struck by a Tsunami in December 2004. A number of farmers lost their land due to submergence and have turned to other opportunities. A number of fishermen have taken up tourism related activities.

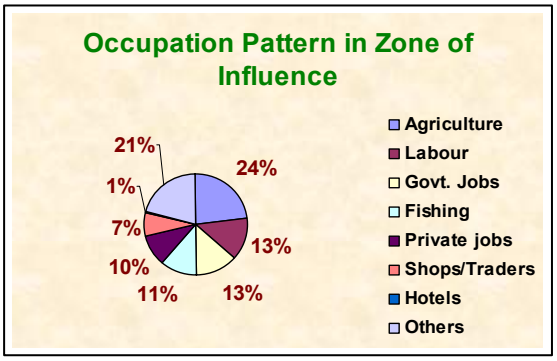

Figure 1: Occupational patterns of locals near MGMNP Source: Kulkarni et al., 2004

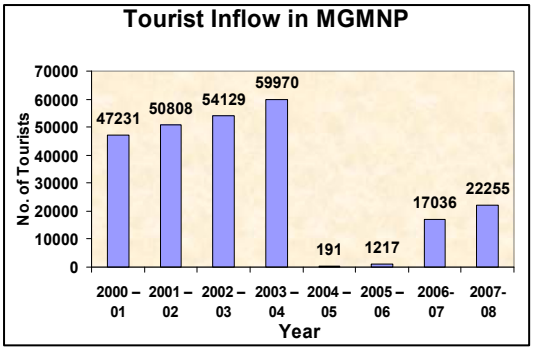

Fig. 2: Tourist inflow to MGMNP.

This Park is an important tourist destination. The inflow of tourists was adversely affected by the Tsunami but in subsequent years the inflow increased again (Figure 2). Though the number of tourists visiting the Marine National Park appears to be still less than 50% of visitors in 2003-04, but the number of tourists visiting Wandoor in 2007-08 was higher than in 2004-05. Two new tourist attractions (New Wandoor beach and Mahua Dera beach) were identified and developed by the local people. Even without proper record, increase in the number of tourists was confirmed by the local people and the Park authorities.

Objective

The objective of the present study was to evaluate measures taken by the Park authorities to address the expectations of the local communities residing in the vicinity of the Park and to involve them in the conservation efforts being taken up in the MGMNP, Wandoor.

Methodology

Four villages (Wandoor, Guptawara, Hashmatabad and Manglutan) fell in the zone of influence. In addition to collection of basic data on the socio-economic profile of these villages, a survey was conducted to understand the extent of

- Awareness about the MNP
- Its objective and impact on occupations
- Their perception about changes taking place
- Their expectations
- Relation with Park Authorities
- Initiatives by the Park Authorities

A questionnaire was developed and interviews were the main tool of data-collection. Stratified random sampling design was used. Sample size of each stratum was based on population as well as the relative importance. Strata-wise percent distribution of sample size is depicted in Figure 3.

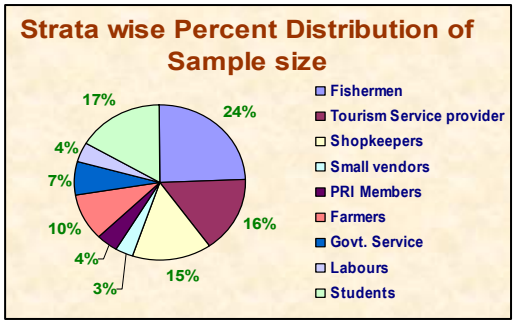

Figure 3: Occupations in the zone of influence of MGMNP.

Results and Discussion

It is revealed from Table 2 that there has been anincrease in economic activities particularly in the post-tsunami period. The number of bus services from Port Blair to Wandoor has almost doubled. The number of private taxis visiting Wandoor per day is presently around 50. The numbers of lodges

and restaurants did not increase much, probably because tourists visit this area during day time for enjoying the beach, swimming, snorkeling and viewing marine life. Local tourist services have also increased from nil to 12. It is quite evident from this Table that local people have realized the potential of tourism as an important livelihood option and therefore not only have they identified new areas of tourist attractions but have also acquired loans from Bank mainly to purchase boats for tourism purpose.

Activity	Pre 2000	2000 -04	2004 -08
Restaurants & Lodges	3	5	6
Ration shops	1	2	3
Bus Service (No. of trips)	16	16	28
Schools	2	2	2
Tourist Services	Nil	Nil	21
Other commercial Establishments	7	8	12
Loans availed for boat	Nil	Nil	37
New tourist Areas identified by local people	Nil	Nil	2

Table 2: Pattern of emerging economic activities

Other important findings of the survey are as follows:

- About 93 % of the local people were aware of the objectives of the establishment of MGMNP in some form or the other. Of the total people interviewed, 66 % knew that the Park was constituted for protection of marine life, 22 % think that the purpose was for promoting tourism and 5% think it to be protection of Wildlife. (Figure 4).

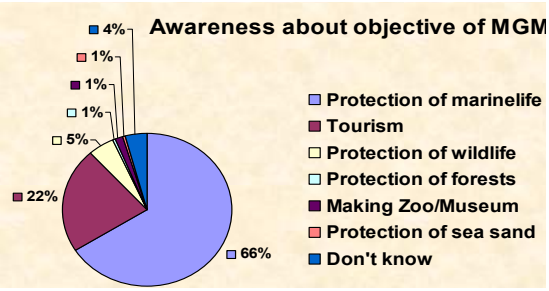

Figure 4: Awareness of the MGMNP.

- On effect of establishment of MGMNP on their occupation, 38 % responded that it has adversely affected their occupations. Of this 91 % were fishermen as fishing is not permitted inside the Park and they have to go to far distances for fishing. Thirty six percent responded that the establishment of the Park has favorably affected their occupations. These include mainly tourist service providers, shopkeepers, small vendors etc. Four percent did not respond while remaining feels unaffected by the establishment of Park.
- About 99 % of the people interviewed were aware about the purpose of tourists visiting Wandoor. Of them, 65 % knew that tourists were coming for viewing marine life, 33 % think that they come for enjoying beaches and nature and 1 % think that wildlife is the major attraction for tourists.
- 95 % view the Park authorities' behaviour towards them to be good and supporting. They expressed that there is regular interaction between them and Park authorities. Five percent (mainly fishermen) complained about occasional harassment.

Following were the main reasons for discont among the local communities:

- Ban on fishing inside the MNP
- No proper berthing place for fishing boats
- Occasional harassment by Forest/Police personnel within MNP
- Assurance of development made at the time of creation not fulfilled
- After Tsunami
    - Fish catch declined tremendously
    - Agricultural land also affected
    - No alternative means of livelihood except Tourism related jobs
- Recent restriction imposed on tourist boats plying to Mahua Dera beach, which is a new site with a beautiful beach and rich coral diversity attracting a large number of tourists. The site has been closed temporarily, which generated a lot of discontent since a number of fishermen turned tourist service providers had taken loans to buy motorized boats for tourism and faced difficulties in repaying loans due to the ban.

On interviewing people about their expectations from the Park authorities, they expressed following points:

- Permission within MNP
  - To carry tourists in small boats/country boats
  - For fishing
- Safe fishing routes through MNP to be demarcated
- Opening of Mahua Dera Beach for tourism through local tour operators
- Permission for country boats to carry eatables for sale to tourists within MNP
- Employment of local people as
  - Tourist Guides/Guards
  - Labourers
- Permission to open Shops and Restaurants near entrance of the Park

It was revealed during the interviews with Park authorities that they have, after a series of meetings with local village leaders, initiated following actions/measures:

- Safe passage routes for fishing boats through MNP has been demarcated
- Alternative berthing site for fishing boat has been identified outside MNP in consultation with stakeholders
- Fish landing facility is being developed by Fishery Department
- Additional Island (Alexendra) has been opened for tourism
- Formation of eco-development committee is in final stage
- Employment of local youth in seasonal works
- Agreed to
  - provide space to small vendors to run their shops near the entrance of Park
  - provide training and employing unemployed youth as tourist guides inside MNP
  - open Mahua Dera for tourism
  - permit boats of local tour operators inside MNP after clearance of certain legal requirements
- These initiatives will be within the legal framework of existing Acts and Rules

It is evident from the survey done that the potential of tourism is realized by local people. As a result they are identifying new areas for tourism and also making investments. However, they need support of the Administration, particularly the Forest Department. In response the Authorities have initiated people's involvement in conservation efforts through alternative livelihood options.

Abstract Underappreciation of the true economic value of coral reef resources is a major problem in developing countries like the Philippines leading to a lack of accounting and accountability in policy and development decision-making. This paper aims to highlight the vital need to integrate economic valuation in coral reef management and in integrated coastal zone management. It uses the total economic value framework, and argues that much of the economic values of coral reef resources have not been properly demonstrated and expressed in the market and policy making, thereby resulting to over exploitation, damage and decimation of coral reefs. Mechanisms on how to demonstrate such economic values (like entrance fees, conservation fees and others) and policies towards their capture are crucial aspects of integrated economic valuation. A few cases in the Philippines show that this is possible and can provide a good framework in helping attain sustainability and conservation of such national treasures.

Key Words: integrated economic valuation, coral reef management, economic values

Introduction

Coral reefs are highly productive and valuable marine resources and home to thousands of species. They provide habitats and food sources for countless organisms and reef-based tourism/ eco-tourism is a major source of livelihood for various coastal communities. Other benefits include coastal protection, biodiversity and the reefs' value as climate change indicators. The economic value of coral reefs is important, from direct use to indirect use and non use values (Table 1; Cesar 2000; Subade 2005).

However, coral reefs are threatened by over fishing, destructive fishing, coastal development, marine-based pollution, climate change impacts, and many other global and local factors. Philippine coral reefs cover an estimated area of 27,000 sq km, and are considered to under threat (BFAR-NFRDI-PAWB 2005). A large proportion of the impact stems from anthropogenic causes, caused by the very high population density of the country. Over-fishing, destructive fishing practices (blasting and the use of toxic substances) and sedimentation top the list of these impacts.

Thus, most of the country's coral reefs are in a degraded state, with over 70% with poor or fair quality and quantity of coral cover; and only 5% in excellent condition (BFAR-NFRDI-PAWB 2005).

Most reef areas in the Visayan Sea Basin, and in gulfs and bays are heavily overfished. In the Visayan seas, particularly in protected areas, poaching and fishing-related threats are the worst threats to coral reefs, followed by sedimentation, tourism related-activities, crown-of-thorns starfish infestations, and coastal development. Fishing and gleaning on coral reef areas account for 10-15% of the country's total fish catch (BFAR-NFRDI-PAWB.2005).

Table 1. Economic Values of Coral Reefs

DIRECT USE VALUES	INDIRECT USE VALUES	NONUSE VALUES

Direct benefits Goods & Services, Usually marketed values, like fish, sea cucumber, and scuba diving (with dive fees)	Functional benefits Environmental and ecosystem values - nutrient retention - flood control - storm/ coastal protection -external ecosystem support	Bequest Existence Option Quasi-option

A recent compilation of studies through time by the Philippine Coral Reefs Information Network (Philreefs 2008), showed mixed trends on the country's coral reefs indicator such as hard coral cover, fish biomass and fish abundance. Generally marine protected areas (MPA) sites have had increasing or no net change trend, while most non-MPA sites have had decreasing or no net change trend.

Usual Valuation Problem

Failure to account adequately for their economic values in development decision making could be considered a major reason for coral reef decline. Since natural and managed environmental/ marine resources are not bought and sold on markets, they are generally ignored in private and public development decisions. Coastal development is often preferred over pristine/preserved coastal habitats because only market values are considered. Inclusion of non-market values might have caused many coastal development projects appear less attractive investment options.

Reef fisheries are an over-capitalized sector where resources are invested to give lower net benefits. Because environmental/degradation costs are usually not included in cost/benefit calculations, the returns even from an over-fished fishery appear higher than they are in reality. Another undervaluation example is destructive fishing - fines and penalties are not based on economic values of damages caused, thus the activity persists.

Need to Integrate Economic Valuation in Coral Reefs Management

Coral reefs management therefore should not be devoid of economic valuation. Moreover, coral reefs research needs to include economic valuation as an integrated component and not just an after thought.

Economic valuation involves three major phases (Fig. 1). First demonstration of coral reef economic values (Georgiou et al. 1997). Then appropriation, which is capture of coral reefs economic values through appropriate policies and mechanisms (Georgiou et al. 1997). Third is utilization, which concerns the use of measured coral reef economic values and/or captured coral reefs economic values in IEC, decision making and in financing of conservation

The economic valuation of coral reefs, i.e. the demonstration, appropriation and utilization of their economic values is a crucial impetus to attaining their sustainability and conservation.

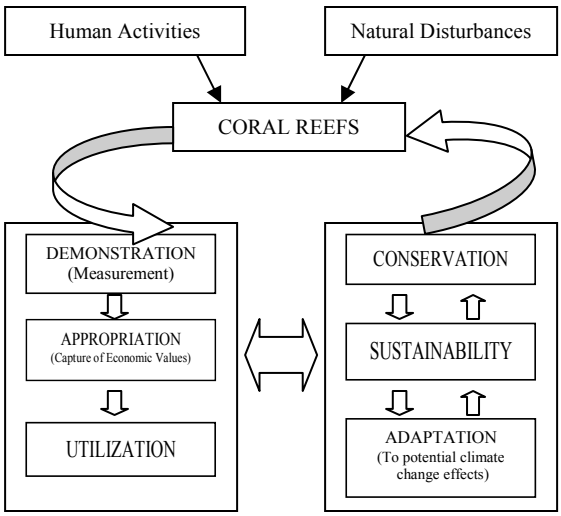

Figure 1. Integrated economic valuation in coral reefs management

Integrated Economic Valuation of Coral Reefs

Improving coral reef management, in the context of Integrated Coastal Resource/Zone Management involves the integration of economic valuation and makes integrated economic valuation or (IEV) an inseparable part of sustainable ICZM or ICRM. IEV provides researched-based incentive/ disincentive mechanisms to: (i) attain sustainability, and (ii) generate financing source for conservation and / or coastal resource management. IEV does not end at mere study/ measurement of economic values but provides mechanisms to capture or appropriate them. IEV transcends policy analysis towards policy advocacy.

In the ICZM or ICM developed at various sites by the UNDP-funded Partnership in Environmental Management of the Seas of East Asia (PEMSEA), economic valuations were embedded in various stages such as: preparing, initiating, developing, adopting, implementing, refining and consolidation of management plans (www.pemsea.org).

Examples of IEV in Coral Reef Management

The integration of economic valuation in coral reef management is evident in the examples of Mabini and Tingloy, Batangas and the Tubbataha Reefs

National Marine Park, a UNESCO World Heritage Site, where scuba diving tourism is a major activity.

Economic valuation was undertaken by a WWF-Philippines-led team to demonstrate and appropriate coral reef economic values mainly through divers' fees. A conservation fee surcharge or an annual diver's pass was collected from divers (Padilla et al. 2005). The IEV process framework involved: Project design, marketing the project to LGU officials & stake holders, research /surveys, sectoral briefings & consultations, drafting of ordinance, stakeholders consultations, refinement & finalization of draft ordinance, provincial approval of the ordinance, IRR formulation, implementation, monitoring & evaluation. Over a period of eight months (September 2003 to May 2004) a total of 1.3 million pesos was collected from conservation fees. Proceeds from the collection were used for incentive rebates to boatmen (who are fishers) and for financing law enforcement through the Bantay Dagat (Sea Watch) that protected coral reefs and other coastal resources.

At Tubbataha Reefs NMP, a similar process of economic valuation was also undertaken, though the implementing rule was for the Tubbataha Management Office (TMO) to collect the conservation fees both from the divers and the boat operators. A "willingness to pay" survey was undertaken that determined the entrance fees and conservation fees per diver as follows US$50 for foreign divers and US$ 25 for local divers : (Mejia et al. 2000; Tongson and Dygico 2007)

The realized revenue is allocated among a seed fund for conservation, core park administrative costs, and livelihood of adjacent communities in Cagayancillo, Palawan.

Resource Rent for Resource Conservation

Resource utilization generates resource rent (benefits or revenues less costs), alternatively called economic profit or profit. This rent rightfully belongs to the resource, and should be used to conserve it and allow it to replenish, thereby attaining sustainability.

ICZM should therefore incorporate IEV which is a major factor (perhaps "the key?") towards successful and sustainable ICZM (MPA). IEV can assure MPA sustainability and thereby provides sustainable financing mechanisms for marine conservation.

Abstract. The five-island municipality of Tingloy is a popular diving site known for its rich coral reefs. However, these reefs are being threatened by man-made stresses and natural disturbances. A monitoring framework was developed through the integration of scientific and indigenous knowledge in determining and assessing the present status of coral reef environment. One of the benefits of the developed monitoring framework is the empowerment of the fishermen. Institutions and fishermen in the area in cooperation with the academe provided the major backbone of the framework. The fishermen were interviewed, trained and participated in the whole year monitoring of the coral reef environment. The monitoring framework developed served as an overall guide for monitoring activities and the data gathered served as the baseline information of the coral reef environment in the area.

Key words: coral reefs, fishermen, monitoring framework, baseline information, Tingloy

Introduction

The Philippines is blessed with one of the most diverse coral reef ecosystems in the world as it lies in the region known as "The Coral Triangle". However, Philippine coral reefs are increasingly threatened ecosystems. Coral cover is rapidly declining, fish populations are low and reef productivity dropped by one-third during the last decades (Jameson et al. 1995). The damage that occurs to coral reefs is usually the result of natural and man-made interference.

In Luzon, one of the most extensive coral reef ecosystems which is a favorite destination of scuba divers is found along the municipality of Tingloy, Mabini and its vicinity. Tingloy is located in Maricaban Island, Batangas, 120 km south of Manila. Tingloy is situated in the southern coast, and the coral reefs are found along Batangas Bay and Maricaban Strait . The western side of Tingloy (e.g. Sepoc point., Sombrero and Caban islands), is considered one of the best diving sites in the area (Uychiaoco and Aliño 1995). The coral communities of Mabini and Tingloy are said to have traditionally supported rich near-shore fishing and in recent years, a growing tourism industry. In the early 80's however, increased fishing effort using destructive methods, uncontrolled development of the land, increased visitation by scuba divers and day-trippers and increased pollution (solid and liquid waste), began to threaten the coral reef ecosystems of these areas *(*White and Vogt 2000).

The WWF-Philippines (World Wide Fund for Nature) has been implementing conservation activities in Mabini and Tingloy since 1998. It started by setting up community-based, multi-sector inter-municipal council (MATINGCADC), which it envisions will eventually manage the area's rich marine resources. To further ensure this, the project strengthened the coastal law enforcers, "Bantay Dagat" that the local council has organized. With the success in the enforcement efforts of Tingloy to curb illegal and destructive fishing activities, members of the municipal council, Sangguniang Bayan who are also members of the local council, MATINGCADC, are now considering on identifying and declaring certain areas within their political jurisdiction as community-managed municipal marine reserves (Dumaop 2000).

For the past 20 years, much has been done on coastal and reef management in the country, involving government, non-government organizations, local communities and resource users with emphasis on communities' participation in the rehabilitation and conservation programs (White and Vogt 2000; Gutierrez et al. 1996; Fernandez, Matsuda and Subade 2000). There has been an increasing level of participation by local communities and resource users, particularly the fishermen in coastal management across the

country, as evidenced by several cases such as the stories of Apo Island, Banate Bay (Fernandez et al. 2000) and others. In most of those projects, coastal management and monitoring has been done mainly by scientists, and focused on biophysical and chemical aspects. Moreover, most of the monitoring guidelines and techniques were determined by the scientists. This situation makes it difficult for fishermen to be actually involved in monitoring activities. Thus, local participation would usually be limited to patrolling while monitoring would be largely done by the scientists.

There is therefore a need of encouraging participation down to the grassroots level for monitoring and assessment since it is through this that one could determine the status of the coral reef ecosystem and the effectiveness of a policy, a program, or management activity being implemented. This study aimed to facilitate and encourage community participation in the development process of the integrated methodological framework for environmental monitoring of coral reefs in Tingloy, Batangas. It also integrated scientific and indigenous knowledge in determining and assessing the present status of coral reef, reef fish and water quality in the area. The framework developed could also serve as an overall guide for the monitoring activities that was undertaken by the coastal community. The development of methodological framework for environmental monitoring of coral reefs in Tingloy, Batangas, provided a good venue for the expression of community's knowledge and participation in the formulation of monitoring plan for the management of their marine resources.

The Research Process

This study was conducted in the five islands of Tingloy, Batangas involving the community and different institutions for the rehabilitation and conservation of marine resources. Figure 1 shows the conceptual framework of the study. The first component is the community which composed of the fishermen, who are the main residents, and the local government unit (LGU) in the area. The second component is the organization of institutions that were equally important such as the Provincial Government Environment and Natural Resources Office (PGENRO), the academic institution and the Kabang Kalikasan ng Pilipinas or the WWF-Philippines. The PGENRO and the academe provided the scientific knowledge in the environmental assessment while the role of KKP-WWF was measured through its past and present efforts as well as future plans for the sustainable management of the aquatic ecosystem. The third component is the coastal environment specifically the extensive coral reef ecosystem of Tingloy.

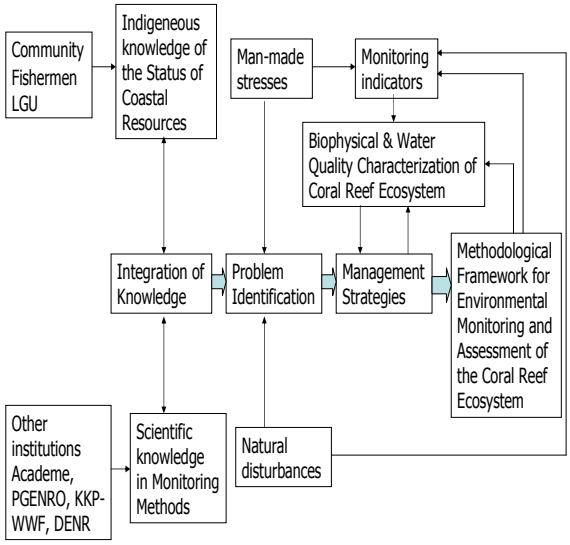

Figure 1. Conceptual framework of the Study.

The framework could be viewed as a system with several components, interacting to come up with an integrated methodological framework for environmental monitoring. The methodological processes for the development of the said framework were shown in Figure 2.

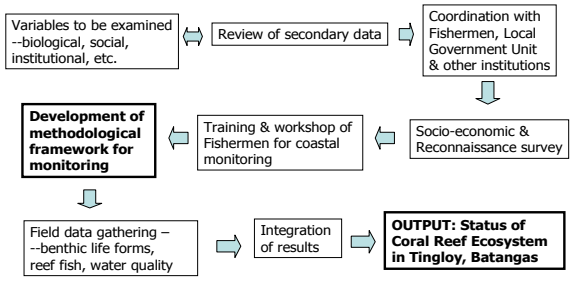

Figure 2. The research process for the development of the framework.

The individual survey was conducted over a 5-week period from June to July 2001 in Tingloy, Batangas. To gather the needed data, a structured and open-ended interview schedule was administered to the fishermen after it was translated to Tagalog and pre-tested in Barangay Sulo, Mabini. The questionnaire consisted of 10 pages divided into the following five sections: 1) demographic and socio-economic characteristics of

fishermen, 2) fishing and resource management practices including fishing effort and catch, 3) knowledge, 4) perception, and 5) attitude. In the last part of the questionnaire, the fishermen were asked if he is willing to participate in monitoring of coastal resources and the reason for his answer.

A two-day training on coastal monitoring was conducted for the fishermen. Out of the 109 fishermen interviewed, eight participated in the training-workshop. The five criteria for the selection of participants in fishermen's training were: 1) his willingness to volunteer without payment in the monitoring, 2) have at least a total score of 100 out of 128 points (on the perception, attitude and knowledge questions), 3) must agree or strongly agree to the establishment of marine reserves, 4) physically fit, and 5) able to read and write. One of the limitations in the number of participants is the limited funds considering that the activity only provided food and transportation expenses and no extra allowance was given.

The data from the social survey provided input in the identification of the major problems to be addressed in monitoring. Out of the 26 problems identified, six major problems were identified with the fishermen for environmental monitoring The six major problems identified were poverty or low income among the municipal fisherfolks, overfishing or overexploitation of resources, habitat degradation due to dynamite and cyanide fishing, pollution due to the presence of considerable amount of garbage and oil in the coastal waters, and storms or typhoon.

Based on the results of the reconnaisance conducted, five (5) sampling sites were identified for coral cover, reef fish and water quality assessment of the study. The five sites selected can give a representative estimate of the status of the coral reef ecosystem in Tingloy, Batangas. The criteria for the selection of the sites are as follows: 1) serve as a site of baseline data of the status of coral reefs in Tingloy 2) will serve as one of the major sites for future monitoring activities 3) serve as one of the possible sites for the establishment of marine reserve and 4) serve as one of the possible sites for protection and rehabilitation programs. Fishermen preferences of the sites as a fishing ground and where oil spill was observed were also considered. The results of manta tow survey was integrated in the focus group discussion to finalize the selection of sampling sites and appropriate sampling time for the wet and dry season of various physical, biological and chemical parameters of the study.

Coral and reef fish surveys were done during the month of March. Two fishermen were assigned for each site for the coral and reef fish survey. A line-intercept technique and snorkel survey were used by the divers and fishermen, respectively in the assessment of coral reef and reef fish. Based on Gomez and Alcala (1978) studies, coral cover was categorized as Excellent (75-100%), Good (50-74.9%), Fair (25-49.9%), and Poor (0-24.9%).

Water sampling of coastal waters was quarterly scheduled in the months of August, November, February and June. Sample collection for each month was carried out by two fishermen for all the five sites over a one day period. Microbial, physical and chemical attributes of the coastal water were determined with assistance from PGENRO.

Methodological Framework for Monitoring

The framework was developed through the participation of the community particularly the fishermen and various institutions (Table 1).

Status of Coral Reef Ecosystem

The methodological framework was then applied to determine the status of the coral reef ecosystem in Tingloy, Batangas. Five sites were monitored for coral cover, reef fish and water quality.

Coral Cover

Sites chosen for the survey were the Caban reef, Macawayan Reef, Bonito Reef, Pisa Reef and Sto Tomas Reef. A coral reef assessment using the LIT by divers and snorkel survey by fishermen. Gomez and Alcala (1978) categorization was used.

All five sites were categorized in fair condition by the fishermen survey. On the other hand, diver's survey showed only two sites, Caban reef and Makawayan reef in good condition while the rest of the sites were in fair condition. Both sites had high live hard coral cover among the selected sites thus it can be said that areas in Caban and Makawayan are recommended sites for establishment of marine reserves.

Fish Biomass

Among the five sites, Caban reef (59428.21g) has the highest fish biomass while Pisa reef (12,372.34g) has the lowest. Other reef areas are as follows; Bonito reef (49900.34g), Makawayan reef (36222.93g) and Sto. Tomas reef (25183.46g). Fish biomass could not be determined from the fishermen survey because it requires that fish be identified at the species level.

Table 1. Integrated methodological framework for environmental monitoring of coral reefs ecosystem and social system in Tingloy, Batangas.

ISSUE OR PROBLEM	CAUSES	POSSIBLE INDICATORS	MANAGEMENT STRATEGIES	WHERE TO MONITOR	WHEN TO MONITOR	MONITORING METHOD	PERSON(S)/ INSTITUTION INVOLVED
Poverty or low income of municipal fisherfolk*	Too many fishermen, overexploited resources, low catch, management practices	Income*, no. of fishers*, health condition	Alternative livelihood*, fishing regulation through licensing	Per municipal barangay	Once a year	Social survey	LGU, Academe, NGO, DENR
Overfishing*	Changes in fishing effort, natural disturbances, changes in coral cover, management practices	Fish sizes and abundance	Harvest regulations (MPA/Zoning, seasonal closure, gear restriction, species restriction), patrolling and enforrcement*	Inside and outside MPA, representative sites of the Tingloy	Wet and dry season	Fish visual census	Fishermen, Academe, NGO
	Increase in fishing effort, management practices like MPA enforcement	Fishing effort; catch per unit effort*		Per municipal barangay	At least once a month	Fish catch monitoring	Fishermen, Academe, LGU, NGO
Habitat Degradation*	Destructive fishing methods, natural disturbances, management practices like MPA	Coral cover*	Education campaign, patrolling & enforcement*, harvest regulations (MPA, seasonal closure, gear restriction, species restriction)	Inside and outside MPA, representative sites of Tingloy	Once a year	Manta tow, snorkel survey	Fishermen, Academe, NGO
Pollution (solid waste and sewage)*	Waste disposal practices, management practices	Garbage*	Waste management (proper disposal system), Patrolling and enforcement*, Information campaign for proper sanitation	Representative sites of Tingloy	Every quarter of the year	Water quality analysis particularly on ammonia, nitrogen, phosphate, DO and BOD	Fishermen, PGENRO, Academe, NGO
	Lack of toilet facilities, management practices	Cases of diarrhea		Representative sites of Tingloy especially Sto. Tomas site.	Every quarter of the year	Water quality analysis particularly on Total and Fecal Coliforms	Fishermen, PGENRO, Academe, NGO
Pollution (oil spill)*	Industry and ships oil spill, management practices	Oil spill*	Lobbying for waste reduction from oil refineries and ships*, patrolling and enforcement	Representative sites of Tingloy especially Sto. Tomas	Every quarter of the year	Water quality analysis particularly on Oil and Grease	Fishermen, PGENRO, Academe, NGO
Pollution (sedimentation)	Loss of mangrove areas, deforestation, management practices	Coral cover	Mangrove reforestation, replanting of trees or vegetation in the upland	Representative sites of Tingloy especially Sto. Tomas	Once a year	Manta tow, snorkel survey	Fishermen, Academe, NGO
	Same as above	Siltation		Same as above	Every quarter of the year	Water quality analysis especially TSS	Fishermen, PGENRO, Academe, NGO
Storms and/or global warming*	Natural disturbances, increasing CO_2 level	Coral cover*	Reduce man-made stress to enable the environment to recover more easily	Representative sites of Tingloy particularly Bonito	Once a year	Manta tow, snorkel survey	Fishermen, Academe, NGO

Legend: * - identified by fishermen

Fish Abundance

About 31 families were recorded by the divers in all the five sites while the fishermen identified 25 families. Survey showed that Makawayan reef has the highest fish abundance, followed by Caban reef. Pisa reef and Sto. Tomas reef has the lowest fish abundance. By family, Pomacentridae had the largest contribution to the mean biomass, accounting for more than 30% of the total biomass for each site. It is also the most numerous fish group per individual counts for all sites. Fishermen's survey on fish abundance per individual counts was also highest for Pomacentridae.

Fishing Effort and Species Caught

Most common fishing gear used was hook and line, aboard small and mostly non-motorized boats. Fishing was done almost everyday averaging 3-5 hours. Fish caught were mostly small pelagics such as skipjack tuna, mackerels and scads.

Coastal Waters of Tingloy, Batangas

In general, the water quality of coastal waters of Tingloy was still within the DENR standard for Class SA coastal and marine waters except for some areas in the total and fecal coliforms standard. Bonito and Sto Tomas are way beyond the maximum DENR standard for coliforms. All sites have high total suspended solids value for all quarters which indicate the degree of sedimentation in Tingloy. Among the five sites, the coastal waters in Sto. Tomas exceeds the allowable limit for Class SA marine water. Sto. Tomas has the highest readings in oil and grease, BOD, and fecal coliforms. It also has a high reading in total suspended solids and total coliforms. The level of oil and grease in Sto. Tomas showed that Tingloy is not spared from oil spill in Batangas. With these results, resort establishment is not advisable along the coast of Sto. Tomas.

Conclusion and Recommendations

The development of methodological framework for environmental monitoring involved the participation of coastal communities (i.e. fishermen) and institutions. However it appears that the fishermen need more practice for biological survey of benthic lifeforms as well familiarization with the scientific description of these substrate cover. In addition, consultation with the fishermen are necessary to improve the existing method or in trying another method like the point-intercept transect, whichever suits their capability.

In retrospect, the benefits in the development of the methodological framework are the following: (1) The community and institutions are given a chance to participate and share their indigenous and scientific knowledge; (2)The fishermen are empowered in the development process of the framework; (3)The baseline characterization of the coral reef ecosystem is determined through the combined efforts of the community; (4) The framework could serve as a guide that can be applied by other coastal communities. Modifications may be made due to differences in human activities in the area.

Limitations are as follows: (1) Its application in other areas may be limited by the capacity of the fishers in the area. Thus training of these fishermen should be considered; (2) Its application would require going into the different components of the framework and this would entail time and money. However, this framework could give a starting point for the development of other methodological framework in other communities.

(3) Not all indicators were monitored due to time and financial constraint; (4). In this study, some local names of reef fishes were not identified. It is therefore recommended that a study be conducted for a uniform identification of reef fishes with its local name, English name, and scientific name.

Abstract. We used population abundance and size structure data from fishery-independent (visual census) and fishery-dependent (creel surveys) monitoring programs from the Florida Keys and Biscayne National Park to estimate stock mortality rates and current reproductive potentials of the seven most commonly harvested reef fishes. Numerous indicators revealed these reef fishes are currently experiencing unsustainable rates of exploitation. Annual growth in recreational fishing effort compounds this problem. If healthy reefs are Florida's future, exploitation of reef fish stocks must be reduced. Fishery management actions were evaluated that could possibly reduce fishing mortality and increase reproduction potential sufficiently to achieve sustainable stock conditions. Results indicated that, when using only traditional management approaches such as increased minimum harvest sizes or decreased bag limits, rather radical changes will be needed to achieve sustainable stock conditions, and any improvements may be negated by continual increases in fishing effort over relatively short time horizons. We conclude that, in addition to traditional fishery management controls, contemporary measures such as placing a portion of the population under spatial protection will likely be needed to achieve long-term sustainability of Florida's coral reef finfish fisheries.

Keywords: Florida, coral reefs, overfishing, sustainable fisheries

Introduction

The Florida Keys coral reef ecosystem, including Biscayne National Park, is inhabited by more than 400 fish species and supports multibillion-dollar fishing and tourism industries. Over recent decades, reef fish populations have declined owing to a variety of human-related stressors, most notably fishing and habitat alterations (Bohnsack and Ault 1996; Ault et al. 1998, 2005a). These fishes are intensively exploited (Ault et al. 1998, 2001, 2005b) by a rapidly growing human population and recreational fishing fleet (Fig. 1). Biscayne National Park (BNP) is in the process of developing plans to guide resource management decisions for the Park over the next 15-20 years that will contribute to conservation of fish species and their habitats, and sustain a tradition of quality fishing experiences for generations to come. The strategy for fisheries management is being developed cooperatively by BNP and the Florida Fish and Wildlife Conservation Commission (FWC), with input from members of government agencies, area universities, and the public. Fishery management concerns for reef fishes in south Florida are two-fold: (1) declines in the abundance of fish; and, (2) loss of quality fishing opportunities.

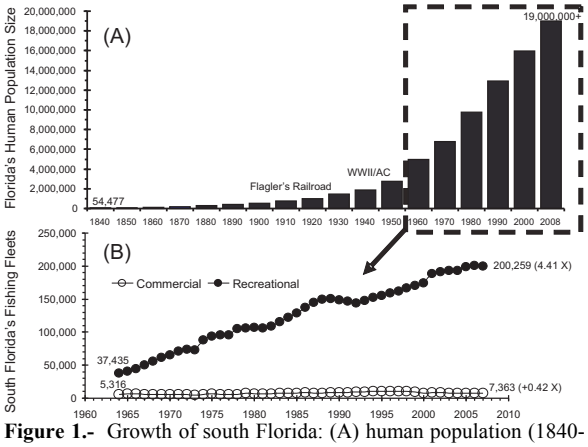

Figure 1.- Growth of south Florida: (A) human population (1840-2008); and, (B) fishing fleets (1964-2007).

To mitigate reef fishery declines, the South Atlantic Fishery Management Council in 1983 and the Florida Marine Fishery Commission in 1984 began establishing minimum size, season, and bag limit restrictions on a number of reef fish species. The current size and bag limit regulations for reef fishes in south Florida have been in place since the late 1990s (www.myfwc.com/marine/regulation.htm). However, the most recent assessments suggest that majority of snapper-grouper species are currently

fished at unsustainable levels (Ault et al. 2005b).

To assist in the BNP management processes, in this paper we assessed the sustainability of key reef fish stocks in BNP in relation to the Florida Keys, Once exploitation levels were identified, we evaluated potential benefits of more restrictive size and/or bag limits in terms of their efficacy to achieve sustainable populations and meet regional resource management goals.

Methods

Data Sources.- Two principal data sources were used, fishery-independent and fishery-dependent. Fishery- independent data were visual census surveys of reef fish species abundance and size structure for the Florida Keys ecosystem, including Biscayne National Park, for the period 2000-2004 (Bohnsack et al. 1999; Ault et al. 2001, 2005b). Fishery-dependent data were creel census surveys conducted in BNP for exploited species abundance and size structure for the two time periods, 1995-1998 and 2000-2004 (Ault et al. 2007).

Sustainability Analysis.- The principal stock assessment indicator variable we used to quantify sustainability status was average length ($\overline{L}$) of the exploited part of the population, the interval between the minimum size/age of first capture (L_c/a_c) and the maximum size/age (L_λ/a_λ) observed in the stock. For exploited species, $\overline{L}$ directly reflects the rate of total instantaneous mortality through alterations of the population size structure (Beverton and Holt 1957; Ehrhardt and Ault 1992; Quinn and Deriso 1999).

Estimates of average length were obtained from length composition data derived from the fishery-independent and -dependent data following the procedure described in Ault et al. (2005b, 2008). Using estimates of $\overline{L}$, total instantaneous mortality rate Z was estimated using the method of Ehrhardt and Ault (1992) and an iterative numerical algorithm (computer program LBAR, FAO 2003). Life history parameters for maximum age, growth and maturity for the reef fish species considered are given in Ault *et al.* (1998, 2005*b*). Additionally, we evaluated the two major components of Z, namely fishing mortality rate F and natural mortality rate M. In this process, we estimated M from lifespan, and F was estimated by subtracting M from Z (Ault et al. 1998).

A numerical cohort-structured model (Ault et al. 1998, 2008) was used to compute several fishery management reference points of stock status, or "*sustainability benchmarks*", including yield-per-recruit (YPR), spawning potential ratio (SPR), and limit control rules. Spawning potential ratio (SPR) is a management benchmark that measures a stock's potential to produce yields on a sustainable basis, and is computed as the ratio of current SSB relative to that of an unexploited stock. Benchmarks used to evaluate sustainable exploitation as a limit control rule were: F_{msy} (F generating maximum sustainable yield, MSY); B_{msy} (population biomass at MSY); and SPR (spawning potential ratio). We defined F = M as a proxy for F_{msy} (Quinn and Deriso 1999).

Bag & Size Limit Analysis.- We used the BNP creel census data to facilitate evaluation of bag limits. Catch and effort data were computed in terms of landings per angler-trip (i.e., number of fish landed and kept per person-trip). Current bag limits were evaluated in terms of percentages of trips that caught more than specific amounts of fish per person.

To evaluate potential gains in population benchmarks through increases in the minimum size of first capture, we conducted a "eumetric" fishing analysis (*inter alia* Beverton and Holt, 1957) for each key reef fish species. This analysis identifies the optimum combination of minimum size of first capture L_c given a particular fishing mortality rate F that results in maximal yields in weight and/or numbers of fish.

Results

Estimates of $\overline{L}$ from BNP creel data for seven principal exploited reef fishes were consistent between the 1995-1998 and 2000-2004 time periods (**Table 1**). The estimates of $\overline{L}$ from the latter time period were consistent between the BNP creel and Florida Keys visual census (Fig. 2). A substantial proportion of fishes observed in the creel census were smaller than the minimum legal size (Table 1). These undersized fish were not included in the computation of $\overline{L}$.

These data, together with the known life history parameters for each of these species, were then used to calculate estimates of current fishing mortality rates, stock biomass, SPR and YPR for each of the key reef fish species. Values of the F/F_{msy} ratio plotted against the B/B_{msy} ratio (Fig. 3) suggest all seven species are being subjected to unsustainable rates of exploitation (F-ratio >1, B-ratio <1; Ault et al. 2008).

We evaluated creel census catches to determine the closeness of catch rates to current bag limits (Table 2). The majority of the hook-and-line trips caught none of the key reef fishes, and only a small fraction of these trips ever reached the current bag limit. The only exception was for hogfish taken by spearfishers, who reached the bag limit on about 10% of the trips.

Given that we found that all seven of the key species are currently being subjected to unsustainable rates of exploitation, we evaluated the potential

impact (in terms of SPR and YPR) of changing the size limits. For these analyses, we assumed that current estimated fishing mortality rates would continue unabated at their most recent levels, and then we increased the minimum size limit to the apparent optimal (i.e., eumetric) level.

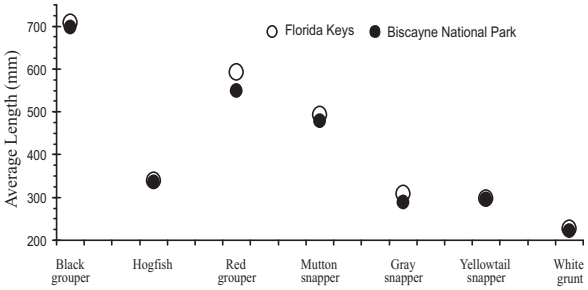

Figure 2.- Average size in the exploited phase for 7 reef fish species in the Florida Keys and BNP.

Summary results of these analyses for the "eumetric" minimum harvest size are given in **Table** 3. The changes in size correspond to a 2-3 fold increase in the age of first capture for most species. This increase in size/age is projected to favorably increase SPR for all stocks to above the 30% SPR federal standard for sustainability.

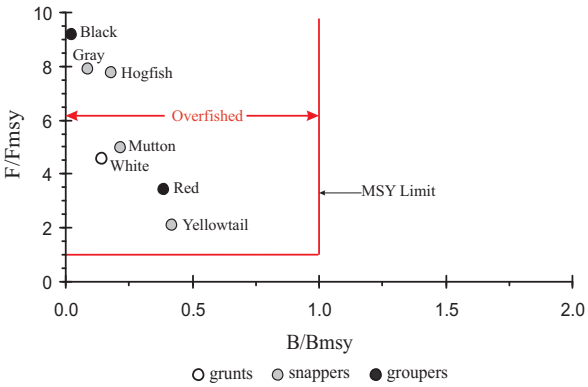

Figure 3.- Plot of F/Fmsy ratio against B/Bmsy ratio for 7 key reef fish species in the Florida Keys-BNP coral reef ecosystem for the years 2000-2004.

The time required for reaching the new equilibrium following implementation of a size change varies among the species, but could be a decade or longer for groupers (Fig.5).

Discussion

There has been a continuous long-term increase in registered recreational boats and fishing effort coupled with human population growth in South Florida. In the last 15 years, the recreational fleet has increased from about 140 thousand registered vessels to over 200 thousand (Fig. 1) and there is nothing to suggest that recreational fishing effort will not continue to increase into the future within the park and the greater south Florida area. Unless some additional restrictions are placed on the recreational fishery, fishing mortality rates for all of the species are likely to continue to increase into the future.

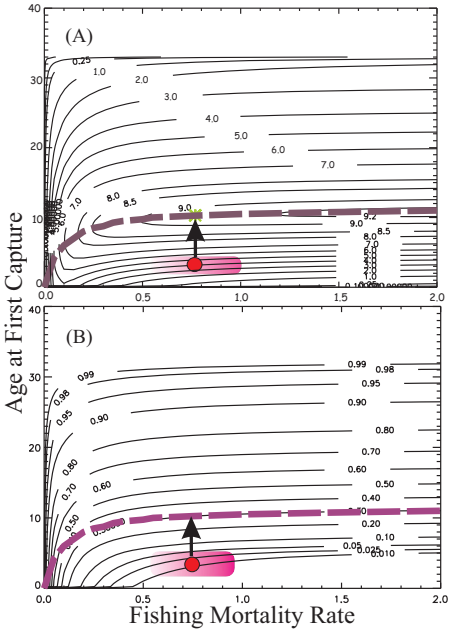

Figure 4.- Black grouper isopleths for: (A) yield-per-recruit in weight (Yw/R); and (B) spawning biomass-per-recruit (SSB/R). Current estimated *F* is shown in the shaded area of each panel, and the arrows denote required changes in size to reach the eumetric line (dashed).

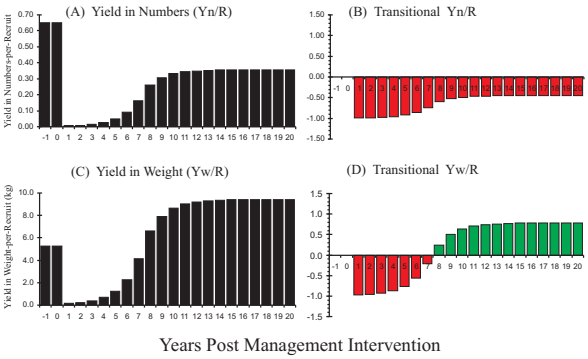

Figure 5.- Transitional dynamics and difference from initial equilibrium for Florida Keys black grouper: (A-B) yield in numbers-per-recruit; and, (C-D) yield in weight-per-recruit, after a eumetric size-limit change.

All seven species analyzed in this study were found to have fishing mortality rates that exceed those which are generally considered sustainable for healthy fish populations. While there has been an apparent stabilization of effective fishing mortality over the past decade, perhaps in response to the various management controls, none of the BNP (or Florida Keys) reef fish populations equaled or exceeded the

minimum 30% spawning potential ratio (SPR) standard generally accepted as necessary for a sustainable fishery stock.

Even though the average number of fish landed per fishing trip for all of the species analyzed was found to be very low, we found a reduction in bag limit may, in some cases, reduce fishing mortality rates. In cases where catch rates are principally low (e.g., black and red grouper, and mutton snapper), reductions in bag limits would have little apparent effect, or would close the fishery. Our analysis suggests that a reduction in bag limits alone will not be sufficient to allow stocks to recover.

On the other hand, increasing the minimum size of first capture could lead to demonstrable increases in yield and in stock spawning potential. The important point suggested by our analyses is that a dramatic increase in the size at first capture is required to move stock spawning levels above those considered minimum for sustainability. This would, *de facto*, make the entire fishery a closed area for several years following the change (**Fig. 5**).This is particularly true for black grouper, hogfish, mutton snapper, gray snapper, and white grunt.

With either increases in minimum size or decreases in bag limits there will undoubtedly be an unintended increase in catch-and-release mortality incurred as both undersized fish and fish in excess of the allowable bag are released. This topic has been thoroughly reviewed by Bartholomew and Bohnsack (2005), who reported that catch-and-release mortalities ranged between 10 and 90% for over 200 species studied. For reef fishes targeted in BNP, release mortality rates would likely average from 10 to 30% from catch-and-release fishing.

Studies as early as Beverton and Holt (1957) and many others (Quinn and Deriso 1999) have shown that the ratio of natural mortality to growth rate of a species can provide a good indication of the rate at which species will recover when exploitation rates are reduced. All the reef fishes analyzed have relatively low M/K values. Unfortunately, this suggests that even if the necessary size were instituted immediately, stocks would not likely reach a sustainable status for at least 10 years.

In this paper we have only considered traditional management tools as the means of ensuring the sustainability of exploited reef fish stocks. While increased size limits have shown some promise, we believe that the only long-term solution will eventually involve multiple control methods including traditional approaches such as limiting the amount of fishing effort and/or restricting sizes to be captured, combined with more contemporary approaches like placing a portion of the population under spatial protection to ensure long-term resource sustainability.

Abstract. Fish of the family Serranidae: subfamily Epinephelinae are some of the most heavily harvested reef fish in the Caribbean. However, large knowledge gaps exist about their reproductive biology. Understanding a species' reproductive biology is critical for species management and provides evolutionary insight into species-specific reproductive strategies. Epinephelinae species possess a diversity of reproductive strategies, comprised of life-history traits which are highly variable between and amongst populations (e.g. size at sexual maturity, spawning duration, sex ratio). For this study, a reproductive histological classification system was refined for application to Bahamian fish populations of: *Epinephelus striatus* (Nassau grouper), *E. guttatus* (red hind) and *Mycteroperca venenosa* (yellowfin grouper). The use of a single classification system on multiple species provided a reliable framework to assess the status of reproductive life-history traits. Spawning seasonality in The Bahamas was described for populations of *E. striatus, E. guttatus* and *M. venenosa.* Spawning for *E. striatus* peaked November through January, while *E. guttatus* peaked in January and *M. venenosa* peak in March and April. The classification system will be used to establish consistent monitoring techniques and the results provide information for future management efforts in The Bahamas and allow for comparison to populations throughout the Caribbean.
Key words: Nassau grouper, red hind, yellowfin grouper, reproductive biology, gonad histology classification

Introduction

The reproductive biology of a fish is defined both by the combination of the species-specific reproductive mode and reproductive traits (Winemiller and Rose 1992, Murua and Saborido-Rey 2003, Morgan 2008). The reproductive mode does not vary between populations and is defined by the combination of the sexual development pattern (e.g. gonochoristic or hermaphroditic) and the gamete production system (e.g. determinate or indeterminate). Reproductive life-history traits (e.g. spawning seasonality and duration, age or size of sexual maturity, and sex ratio) vary between and amongst populations (Winemiller and Rose 1992, Murua and Saborido-Rey 2003, Morgan 2008). All are critical to understand a given population because they provide insight into how different strategies influence gamete production (Winemiller and Rose 1992) and how life-history trait plasticity can greatly alter a population's productivity or reproductive potential over time (Winemiller and Rose 1992, Morgan 2008).

Histological analysis of gonads provides more accurate and specific information to quantify life-history traits than traditional, macroscopic gonad examinations. Balon (1975) and Winemiller and Rose (1992) established that a classification system should also allow for intra-species comparisons for ecosystem based management and evolutionary life history comparison purposes. The use of a single histological classification system on multiple species provides a means to assess the reproductive biology of species that possess different reproductive strategies with variable life-history traits, and allows for comparisons between species.

Species of the family Serranidae: subfamily Epinephelinae (commonly called groupers and hinds) are heavily fished in the Caribbean. Despite their importance, large knowledge gaps exist about their reproductive biology. As with most marine fish, species-specific data is required for Epinephelinae because reproductive life-history traits are variable both within and between species (Sadovy 1996). In The Bahamas, fishery management and monitoring initiatives are focusing on securing consistent reproductive biology and landing data for commercially valuable Epinephelinae species.

Epinephelinae landings, especially *Epinephelus striatus* (Nassau grouper), and to a lesser, but considerable extent *E. guttatus* (red hind), and *Mycteroperca venenosa* (yellowfin grouper) constitute a major portion of fin-fish catches in The Bahamas (Cushion and Sealey 2007). To date, some reproductive life-history studies have been completed on *E. striatus* in The Bahamas (see Sadovy and Eklund 1999 for a review); while no formal studies on *E. guttatus* and *M. venenosa* have been conducted in The Bahamas.

This paper describes the effectiveness of a histology classification system for quantifying reproductive life-history traits and identifying the reproductive maturity stage of Epinephelinae species. The goal was to affirm that the proper criteria and diagnostics were incorporated into the system, so it could be applied to multiple Epinephelinae species that possess different reproductive strategies. The system was then used to determine the spawning seasonality for *E. guttatus, E. striatus, and M. venenosa* harvested in the central Bahamas. The classification system will form the basis for consistent long-term monitoring initiatives in The Bahamas and provide a means to evaluate temporal and spatial differences in Epinephelinae reproductive life-history traits that influence reproductive potential.

Material and Methods

A fishery-dependent monitoring project commenced in January 2007 at a major commercial fish market in New Providence (the most populated island), Nassau, Bahamas to acquire Epinephelinae landings, population, and reproductive biology data (Cushion and Sealey 2007). Data was obtained via monthly monitoring corresponding with the full moon phase (the spawning period of many Epinephelinae). A standard histological classification system was incorporated into the project to evaluate, compare and monitor reproductive traits among Epinephelinae species.

Monthly sampling was conducted at the market from January 2007-April 2008. Length, weight and gonad weight were measured and recorded for each fish. A section of each gonad was collected and preserved in 10% neutral buffered formalin. Gonad sections were later imbedded in paraffin, sectioned and stained using hemotoxylin and eosin following standard histological procedures (Fitzhugh et al. 1993). Gonad homogeneity tests to confirm that a subsample was representative of the entire gonad were previously performed for each species by Sadovy and Colin (1995) (*E. striatus*), Sadovy et al. (1994) (*E. guttatus*), and García-Cagide and Garcia (1996) (*M. venenosa*).

The reproductive biology classification system was adopted (with minor changes) from Lyon et al. (2008). Lyon et al. (2008) outlined a classification system based on previous studies including Moe (1969) and (Brown-Peterson et al. 2006). This system was adopted to classify Epinephelinae species for this study. Minor revisions were made to account for many Epinephelinae being protogynous species (thus having transitional gonads) and the common occurrence of "bisexual" gonads that contain both oogenic and spermatogenic tissue, but for which primary function as either male or female cannot be determined (Sadovy and Shapiro 1987).

Female and male fish were classified using diagnostic features to determine sexual maturity, the leading gamete stage (the most advanced oocyte or spermatogenic stage present), and whether oocytes were recently released (Table 1 a and b). The presence of vitellogenic oocytes indicates spawning will occur within days or weeks. Female spawning indicators are advanced vitellogenic oocytes (lipid and yolk coalescence) that represent the initiation of spawning and fully hydrated oocytes that are indicative of actively spawning fish. Recently spawned females were detected by the presence of post-ovulatory follicles. The end of the spawning season was determined by massive cell atresia (indeterminant spawners) or the lack of vitellogenic oocytes (determinate spawners). Male sexual maturity was indicated by initiation of spermatogenesis and formation of spermatocysts. Males are classified as spawning capable when spermatozoa were evident and filling sperm ducts and lobules.

Fish were classified as transitional if degenerating oogenic and proliferating spermatogenic tissue were present (Sadovy and Shapiro 1987). Fish were classified as bisexual if fairly equal amounts of oogenic and spermatogenic tissues were present, but no sexual function was determined (Sadovy and Colin 1995).

All histological slides for each species were analyzed and classified by two readers. Results were used to determine reproductive class. Also, the percentage of samples in each class was determined monthly and used to estimate the spawning seasonality for each focal species. Months were designated as spawning months if over 50% of the female samples for the month were classified as active or spawning and over 50% of the male samples were classified as spawning capable.

Results

The histological classification scheme modified and utilized for this study provided the appropriate criteria (Table 1) for designation of 96% of gonad samples

Table 1. A histological reproductive classification system and diagnostics for female, transitional, bisexual and male Epinephelinae.

Sex	Class	Diagnostics
Female	Immature, inactive	Primary growth oocytes only, no evidence of prior spawning. Chromatin nucleolus stage (small cells with large nucleus), and initial perinucleolar stage (larger oocytes). Well-organized gonad.
	Inactive, uncertain	Not capable of spawning in distant future & prior spawning unclear.
	Developing virgin, Developing	Cortical alveolar oocytes present. Prior spawning indicators confirm maturity (D). No spawning indicators (Dv).
	Active, mature	Vitellogenic oocytes present, will spawn within days or weeks.
	Spawning, hydrated	Early or late hydrated oocytes or post-ovulatory follicles present.
	Post-ovulatory, spent	End of spawning cycle, majority of oocytes (>50%) experiencing atresia. Post-ovulatory follicles may be present.
	Regressed, inactive, mature.	PG oocytes only, evidence of sexual maturity & recent spawn.
	Regressed, skipped, mature.	Sexually mature but will not spawn in current season, development ended prematurely.
Transitional	Sperm crypts proliferating throughout gonad. Gamete stages from primary spermatocyte through spermatid should be present. Remnant oocytes possibly undergoing atresia. Must possess evidence of degenerating oogenic and proliferating spermatogenic tissue. (Protogynous species only).	
Bisexual	Oogenic and spermatogenic tissues present, but neither is dominant or proliferating. No sexual function can be determined.	
Male	Immature, inactive	Includes males with spermatogonia (SGG) and no evidence of spermatogenesis (SG).
	Developing virgin (only gonorchoristic species)	Spermatogenesis begins; spermatocytes present & no prior indicators of maturity (Dv).
	Developing	Initiation of spermatogenesis and formation of spermatocysts (D).
	Spawning capable	Fish is reproductively active and capable of spawning. All stages of spermatogenesis may be present.
	Spent	Spermatogenesis is ceasing. Some residual spermatozoa present Spermatogonia proliferation and regeneration of germinal epithelium common in periphery of testis.
	Regressed, inactive, mature	Spermatogonia dominate; no active spermatogenesis. Continuous germinal epithelium throughout.

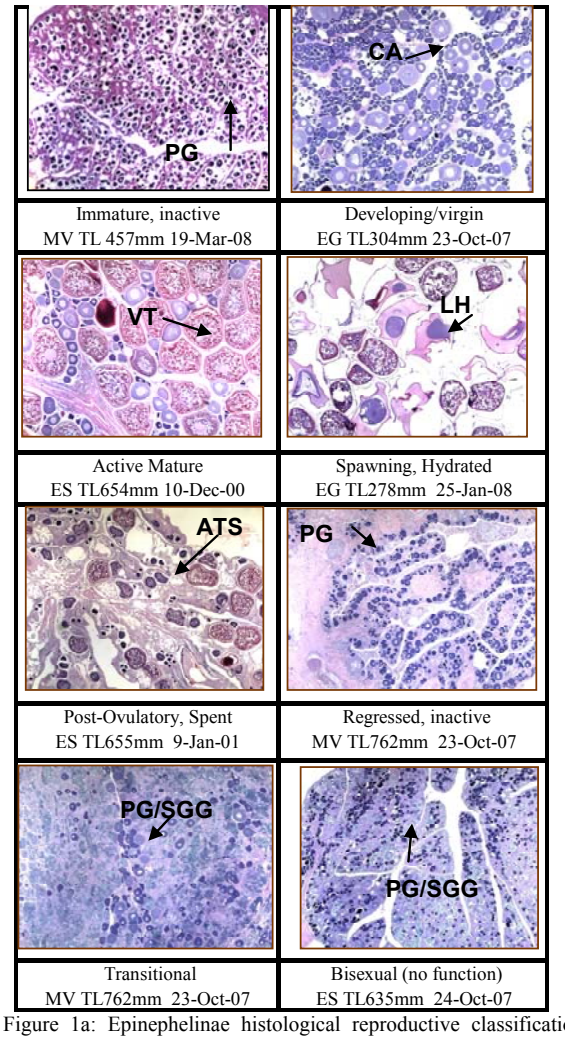

Figure 1a: Epinephelinae histological reproductive classification system for females, bisexual and transitional fish. Reproductive classes, diagnostic features, size and sample collection date are highlighted for female *E. striatus* (ES), *E. guttatus* (EG) and *M. venenosa* (MV). Primary growth (PG), cortical alveolar (CA), vitellogenic oocytes (VT), late hydrated (LH) and atresia (ATS) are highlighted.

(n=675) into a class (Fig. 1 a and b), all species combined. The results of this study corroborate previous reproductive biology studies on the focal species. Gamete production in *E. striatus* is indeterminate and the species is functionally gonochoristic (Sadovy and Colin 1995). *E. guttatus* is a protogynous hermaphrodite with determinate gamete production (Shapiro et al. 1993); while *M. venenosa* is a protogynous hermaphrodite with indeterminate gamete production (García-Cagide and Garcia 1996).

E. striatus samples were typically the most challenging to classify due to ~12% (26 out of 220) of all samples containing both inactive oogenic and spermatogenic tissue. The domination of oogenic or spermatigenic tissue was used to classify these fish, but 4% were classified as "bisexual" because no

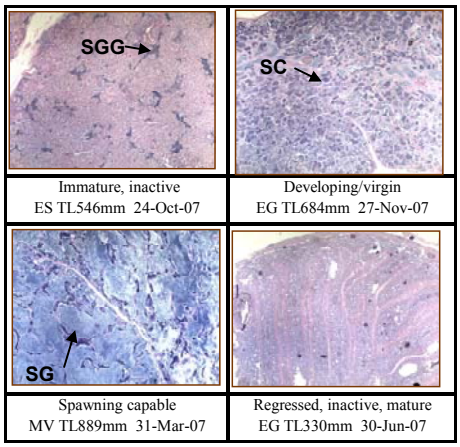

Figure 1b: Epinephelinae histological reproductive classification system for male fish. Reproductive classes, diagnostic features, size and sample collection date are highlighted for transitional, bisexual and male *E. striatus* (ES), *E. guttatus* (EG) and *M. venenosa* (MV). Spermatogonia (SGG), spermatogenesis (SG), and spermatocytes (SC) are highlighted. (Spent male not pictured.)

Table 2. Spawning seasonality for Bahamian Nassau grouper (*E. striatus*), Red hind (*E. guttatus*) and Yellowfin grouper (*M. venenosa*). Samples collected from January 2007- April 2008 in New Providence, corresponding to the full moon cycle. Spawning months were designated as so if over 50% of the female samples were classified as "Active" or "Spawning hydrated" and over 50% of the male samples were classified as "Spawning capable" (Table 1).

Species	**Spawning Years/ Months** *(Sample number in parentheses).*
E. striatus	November 2007 (21) January and February 2008 (27 and 23)
E. guttatus	February 2007 (17) January and February 2008 (22 and 30)
M. venenosa	March 2007* (12 and 28) March and April 2008 (28 and 34)
*Two sampling periods: one at the beginning and one at the end of the month, following the full moon schedule.	

sexual function could be determined. Also, eleven *E. striatus* samples (5%) were classified as "inactive, uncertain". For *E. guttatus* 12 out of the 200 hundred samples (6%) were classified as "inactive, uncertain". For *M. venenosa,* 15 out of the 175 samples (9%) were classified as "inactive, uncertain". For all species, the majority of samples classified "inactive, uncertain" were from the summer, non-spawning months.

Spawning seasonality for the three focal species was analyzed (Table 2). Over 50% of the male and female *E. striatus* samples in November 2007, January and February 2008 were in spawning condition (n=21, 27 and 23, respectively) (no samples were obtained in December 2007). For *E. guttatus*, over 50% of the male and female samples collected in February 2007, January and February 2008 were in spawning condition (n=17, 22 and 30, respectively). *M. venenosa* samples revealed their spawning season to be slightly later. Over 50% of the male and female samples collected during two sampling periods in March 2007 (one at the beginning and one at the end of the month, following the full moon schedule), and March and April 2008 (n=12, 28, 28 and 34, respectively) were in spawning condition. Additionally, 45% of the February samples were in spawning condition.

Discussion

The high percentage of classification for each focal species highlights the cross-utility of the classification system. The system allows for the requisite reproductive biology information to be quantified for Epinephelinae species in the Bahamas. The confirmation *E. striatus* as functionally gonochoristic was supported by the overlap of males and females in all size classes. This is unlike protogynous *E. guttatus* and *M. venenosa*, in that no males were found in the relatively smaller size classes and no females were found after a certain size (unpublished data). The percentage of *E. striatus* that were classified as bisexual, with no sexual function being determined was not unusual. Sadovy and Colin (1995) investigated the sexual development pattern of *E. striatus* and found four mature bisexual individuals and 23% of all samples were immature bisexuals. The classification of 4% of *E. striatus*, 6% of *E. guttatus* and 9% of *M. venenosa* as inactive, uncertain was also not uncommon. These samples were primarily from summer months when fish are not spawning. Inactive and regressed fish are the main classes during this time period and both are typified by compact gonads with primary growth oocytes. Thus, without sufficient evidence of prior spawning (e.g. old hydrated oocytes) it is not possible to confirm regression. Shapiro et al. (1993) investigated sex change and reproduction in *E. guttatus* and could not distinguish between inactive and late, regressed females.

Spawning seasonality for many Epinephelinae and other reef fish is a variable reproductive trait (within and between populations), especially for populations at different latitudes (Sadovy 1996). Spawning seasonality has previously been determined for *E. striatus* in the Bahamas. Colin (1992) found that the *E. striatus* populations off Long Island spawned during the full moon periods of December and January, possibly not during November and likely not during February. This study highlights that *E. striatus* spawning seasonality is slightly variable within the Bahamas. Spawning began in November 2007 and continued through February 2008. However, for *E. striatus,* spawning seasonality is strongly correlated with the lunar full moon as well as temperature, not the month *per se* (Sadovy and Eklund 1999). Colin

(1992) found *E. striatus* spawning occurred at water temperatures between 25.0-25.5°C. Thus, water temperature is likely a strong contributing factor for latitudinal and annual fluctuations in spawning seasonality.

This is the first documentation of spawning seasonality for *E. guttatus* and *M. venenosa* in The Bahamas. Shapiro et al. (1993) found a similar spawning seasonality for Puerto Rican *E. guttatus* populations. Using a gonadal size index and histology, spawning peaks were found in January and February. Meanwhile, *E. guttatus* spawning peaks much later in Bermuda occurring during the full moon periods from May to July (Luckhurst et al. 2004). It is noteworthy that *E. guttatus* spawning seasonality is not as tightly correlated to the full moon (Sadovy et al. 1994), as with *E. striatus* and *M. venenosa*. Thus the monthly, full-moon sampling regime did not likely capture all *E. guttatus* spawning activity in the Bahamas.

Small groups of *M. venenosa* are often associated with aggregations of *E. striatus* (e.g. Whaylen et al. 2004 (Cayman Islands), Nemeth et al. 2004 (USVI)). However, January and February are not the dominant spawning times for *M. venenosa*. Personal communications with fishermen in this study, in conjunction with gonad sampling, confirmed full moon periods during March and April as peak spawning months of *M. venenosa* in The Bahamas. A large proportion of the specimens were spawning capable in February, thus indicating the spawning period may commence in February. In Cuba, García-Cagide and Garcia (1996) found April and May to be the strongest spawning months for *M. venenosa* which is consistent with later spawning at more southerly latitudes.

Because reef fisheries in The Bahamas are multi-species, it is important to implement a system that can be applied to multiple species to ensure that consistent and reliable information is obtained. The fishery-dependent sampling protocol with a standard reproductive classification allowed for the collection and analysis of samples year round. This combination system will provide a means for long-term monitoring of Epinephelinae species to consistently assess reproductive life-history traits and the reproductive potential of populations.

Acknowledgements

Funding for this project came from the University of Miami Department of Biology, The College of The Bahamas Marine and Environmental Studies Programme, Disney Wildlife Conservation Fund and Earthwatch Institute. Thanks to the fishermen and people at Montagu ramp and to Anastasia Gibson and the Department of Marine Resources staff for field assistance.

Abstract: Underwater fish visual census was undertaken to determine juvenile and adult abundance and biomass of commonly occurring reef fish taxa/species at several sites along the major marine corridors in the Sulu Sea. Presence/absence, abundance, and biomass of taxa/species in both stages showed varying patterns within and among sites. Variation in adult abundance and biomass of some species suggests decreasing similarities with increasing distance at some sites while other species showed contrasting patterns with distant sites exhibiting similarities. For juvenile abundance, patterns were similar with those of the adults. Significant correlation between juvenile and adult abundance was observed at some sites. The match and mismatch of spatial patterns of distribution of adults and juveniles of reef-associated fishes are influenced by two major factors. Local water circulation patterns at the different corridors, which potentially disperse egg and larvae within and between corridors shows changing connectivity potential of fish populations. Relatively high species diversity of juvenile and adult fish was observed in areas of high entrainment. On the other hand, disturbance and stresses such as over-fishing and habitat degradation will increase mortality in fish populations at varying stages of their life history and, therefore, reduces the connectivity potential in a range of spatial scales in the Sulu Seascape.

Keywords: reef fish abundance and biomass, entrainment and habitat degradation, spatial and temporal patterns

Introduction

The marine corridors in the Sulu Sea have been proposed to be strategic marine priority conservation areas that help provide the resiliency in the Sulu Sea (Ong et al. 2002). These areas are found at the heart of the Coral Triangle, which has been recognized as the center of highest marine biodiversity (Carpenter and Springer 2005). Regular monitoring of adult and juvenile reef fish abundances serve as crucial proxies to reef conditions and help understand the major determinants of the population structure of coral reef fishes (Booth and Beretta, 2004).

Observations of the changes in reef benthos and community structure of associated fish dovetail with other factors such as hydrography (Cowen 2002) and larval biology (Leis and McCormick 2002) to fully understand the connectivity of reef populations (Cowen et al. 2006). This study presents the dynamics of the reef fish community structure in the marine corridors of the Sulu Sea.

Materials and Methods

A total of 44 transects from five municipality sites covering the three marine corridors in the Sulu Sea were sampled (Mabini and Verde in the Verde Island Passage; Balabac in the Balabac Strait; Cagayancillo and Tubbataha reefs in the Cagayan Ridge) (Fig.1). Survey months were made during the transition periods of the Northeast monsoon (October 2006) and Southwest monsoon (April-May 2006 and 2007). Fish Visual Census (FVC) was used to determine fish assemblages and abundance of adults and juveniles (English et al. 1997). Fish were identified if possible at the species level, their numbers and sizes estimated within an area of $500m^2$ (adult) and $50m^2$ (juvenile) per transect.

Multivariate analyses of spatial pattern of adult and juvenile fish correlation with forcing factors were performed using the ordination technique, non-metric Multidimensional Scaling (nMDS). In addition, Analysis of Similarities (ANOSIM) was carried out to determine significance of generated patterns (PRIMER 6 ver. 6.1.6). This approach examines factors that influence the spatial and temporal patterns

of the reef associated fish communities. From the patterns we can infer insights that will facilitate marine biodiversity conservation measures to reduce the threats on reef health and help in the design of MPA networks.

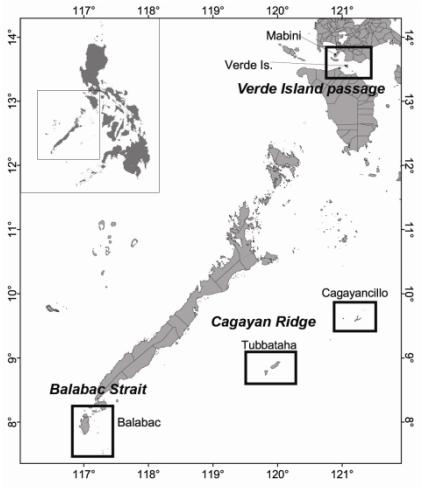

Figure 1. Map of study sites within the three major marine corridors (i.e., *Verde Island Passage, Balabac Strait and Cagayan Ridge* includes Tubbataha and Cagayancillo.

Results

Adult abundance and biomass

Presence/absence, abundance and biomass of taxa/species at adult stages showed varying patterns within and among the municipality sites in the three corridors. Non-metric MDS analysis for abundance showed clear patterns only in between-site category (Fig. 2a). For biomass, ordination analysis provided similar patterns as with abundance. Analysis of Similarity (ANOSIM) of abundance and biomass revealed that factor Site (municipality) was more important than Time (season) (Table 1) suggesting that site-specific attributes are more important forcing factors upon the fish community structure.

Pair-wise comparison for differences in abundance and biomass between municipalities showed large variation between Balabac and Tubbataha (Table 2) especially for the abundances of families Apogonidae, Pomacentridae, Caesionidae Labridae, Lutjanidae, Anthiinae and Acanthuridae. There were more apogonids and labrids (Cheilininae) at Balabac than at Tubbataha but more caesionids, pomacentrids, acanthurids, and lutjanids at the latter than at the former. Between Tubbataha and Mabini/Verde sites, there were more caesionids, acanthurids, lutjanids and serranids at Tubbataha than at Mabini/Verde. Some sites showed increasing similarities with decreasing distance (e.g. adjacent sites Cagayancillo-Tubbataha versus distant sites Cagayancillo-Mabini/Verde) based on the abundances of dominant taxa such as caesionids, acanthurids, lutjanids and serranids. However, distant sites such as Balabac and Mabini/Verde also showed similarities based on the abundances of pomacentrids (*Acanthochromis polyacanthus*) and anthiinids (*Pseudanthias huchtii*). Following Tubbataha in reef fish biomass is Cagayancillo, Mabini, Verde and Balabac. Consistent peaks were observed for Tubbataha for the three intermonsoon seasons, while Mabini was observed to be highest in October. Palawan sites were recorded with highest biomass in the April-May transition periods. In addition, its relatively isolated location in the Sulu Sea (island mass effect; Hammer and Hairy 1981, AMERCO and Andrews 1989) affords the Cagayancillo reefs the high abundance observed.

Temporal pattern in abundance did not differ (April-May 2006 and April-May 2007; $R=0.107$, $p<0.01$) whereas biomass did so slightly. This was attributed to an increase in target species at Verde from 2006 to 2007 and a decrease at Tubbataha from 2006 to 2007.

Table 1. ANOSIM of adult fish abundance and biomass for the five municipalities surveyed over three monitoring periods. Factor with highest R-value contributes more to the community structure.

Factors	R-value	Sig. Level (%)
Abundance		
Time	0.101	0.4^{**}
Site	0.369	0.1^{**}
Biomass		
Time	0.046	6.7^{ns}
Site	0.507	0.1^{**}

The abundant presence of species belonging to the large, top trophic groups (Lutjanidae, Serranidae, Acanthuridae, and Scaridae) resulted in higher biomass in Tubbataha. This was not surprising since Tubbataha is a no-take National Marine Park with strict enforcement resulting in a considerable number of large, top predatory fish whereas Balabac and Mabini/Verde sites are under various levels of exploitation with few smaller marine reserves.

Table 2. Pair-wise test for difference in reef fish abundance (Ab) and biomass (Bm) between groups of municipalities surveyed for the three monitoring periods. R-values approaching '1' indicate large differences.

Groups	R-value		Sig. level (%)	
	Ab	Bm	Ab	Bm
Bal, Mab	0.32	0.34	10.7	9.5
Bal, Ver	0.26	0.43	0.3	0.1
Bal, Cag	0.39	0.41	0.1	0.1
Bal, Tub	**0.75**	**0.91**	**0.1**	**0.1**
Mab, Ver	0.13	0.50	20.6	0.2
Mab, Cag	0.26	0.29	1.4	0.2
Mab, Tub	**0.51**	**0.84**	**0.1**	**0.1**
Ver, Cag	0.35	0.48	0.1	0.1
Ver, Tub	**0.50**	**0.78**	**0.1**	**0.1**
Cag, Tub	0.17	0.50	0.7	0.1

Juvenile abundance

Density (no. per area) of juveniles showed different seasonal pattern compared to adults. Tubbataha, Cagayancillo and Verde peaked in juvenile abundance

during October while Balabac and Mabini peaked during April-May (Fig.4). Tubbataha and Cagayancillo recorded very high juvenile densities, about 6 to 9 times more than the other municipalities surveyed, coincident also with high abundance in adult fish. nMDS analysis for juveniles showed less distinct patterns than that of the adult fish (Fig.2b). In order to identify which taxonomic group of fish drives the variation in abundance, BVSTEP analysis was undertaken. Families Apogonidae and Cirrhitidae were the important fish groups for Balabac and Cagayancillo, while it was Anthiinae for Tubbataha, Verde and Cagayancillo. Gobiidae, on the other hand, was prominent in Cagayancillo and Verde whereas Labridae subfamily Bodianinae was the significant fish group in Cagayancillo and Tubbataha. ANOSIM revealed that both factors Site and Time had very low R values (0.183 and 0.094, respectively) which suggest that the temporal patterns of juvenile abundance are similar among sites. Nonetheless, there appears a difference in the level of abundance between years and seasons at some sites (Fig. 4). There were more juveniles of family Pomacentridae and Anthiinae in April and October 2006 at Tubbataha and Cagayancillo. There was generally higher abundance of juveniles of family Pomacentridae and Anthiinae in 2006 than in 2007 at Tubbataha, Cagayancillo and Verde. These results indicate that recruitment may be seasonal at least at Tubbataha, Cagayancillo and Verde (Fig. 4).

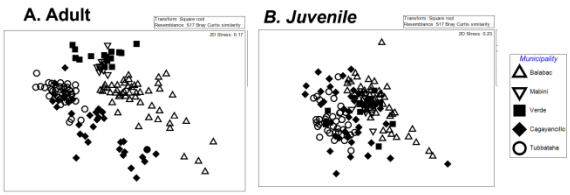

Figure 2. Spatial pattern of (a) adult (b) juveniles fish abundance in 44 transect sites in three monitoring seasons.

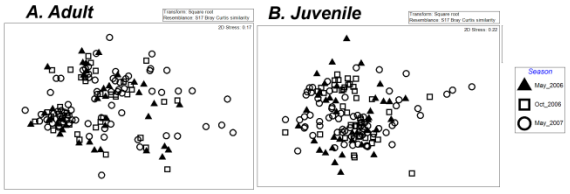

Figure 3. Temporal pattern (a) adult and (b) juvenile abundance in 44 transect sites in three monitoring seasons.

MDS analysis also showed no clear patterns on juvenile abundance (Fig. 3b).

Correlation between adult and juvenile reef fish abundance among the five municipalities for the three sampling seasons revealed low but significant correlations overall ($r=0.4$, $p<0.01$) and per sampling season (May 2006: $r=0.4$, $p<0.01$, Oct. 2006: $r=0.5$, $p<0.01$, and May 2007: $r=0.5$, $p<0.01$). These similarities in abundance trends in adults and juveniles at specific sites can be drawn from patterns in community structure exhibited by dominant families. An example in the study would be Anthiinae identified in the BVSTEP analysis. There was good correlation between juveniles and adults of Anthiinae in Balabac ($r=0.73$, $p<0.05$) and in Verde ($r=0.78$, $p<0.05$). Apogonidae, on the other hand, was highly correlated in Balabac ($r=0.69$, $p<0.05$) but not so much in Cagayancillo ($r=0.14$, $p>0.05$) wherein Cirrhitidae correlated well ($r=0.62$, $p<0.05$). Cirrhitids also significantly showed good correlation in Tubbataha ($r=0.42$, $p<0.05$) together with Bodianinae ($r=0.42$, $p<0.05$). However, this phenomenon is not common in many reef fish families (e.g. Srinivasan and Jones 2006).

Discussion

Some patterns in adults showed decreasing similarity with increasing distance as exemplified by the distant Tubbataha-Balabac sites and proximal Tubbataha-Cagayancillo sites. This pattern could be influenced by processes driving larval dispersal (e.g. Cowen et al., 2000) and thus provides an explanation of the present fish community structure (e.g. Sale and Kritzer, 2003). Beldia et al. (this symposium) have provided data on larval distribution together with oceanographic profiles of the study sites and clearly showed potential larval sources and sinks. However, there were contrasting patterns which showed similarity even in distant sites (e.g. Balabac-Verde). This scenario is completely different and hardly invokes ecological processes as to explain the community structure. Stressors such as fishing and habitat degradation also potentially influence the variation in the patterns. There were differences in the occurrence of target species such as caesionids, acanthurids, labrids and lutjanids among the sites.

Juvenile abundance showed slightly different temporal pattern compared to adult abundance. Recruitment may be seasonal at least in Tubbataha, Cagayancillo and Verde, which peak during October month. However, temporal pattern may be site specific and seasonal trend may not always be consistent between sites (Sale et al., 1984) and seasons (Arceo 2004, Booth and Beretta 2004, Srinivasan and Jones 2006). Among the municipalities, Tubbataha and Cagayancillo recorded very high juvenile abundance than the other sites surveyed, coincident also with high abundance in adult fish (Srinivasan and Jones 2006). This suggests that recruitment is high in Cagayancillo and Tubbataha sites or it has dual functionality of being a source and sink area. Furthermore, Cagayancillo sites

might also act as a sink, receiving larvae from areas farther north such as the Calamianes group of Islands, Cuyo, Agutaya and Apo Reefs via the prevailing water currents during the Northeast monsoon, and receiving larvae from Tubbataha during Southwest monsoon (Fig. 5). Mabini/Verde, on the other hand, may be receiving larvae from Mindoro and Tayabas Bay. This however still remains to be confirmed.

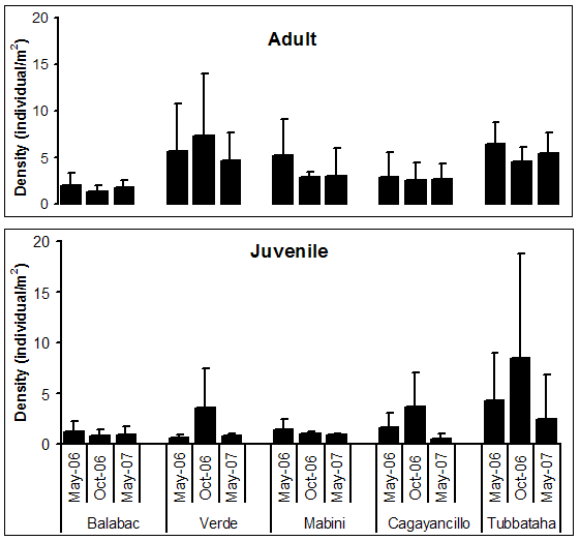

Figure 4. Density of adult and juvenile fish. Recruitment may be seasonal at least in Tubbataha, Cagayancillo and Verde, which peak during October.

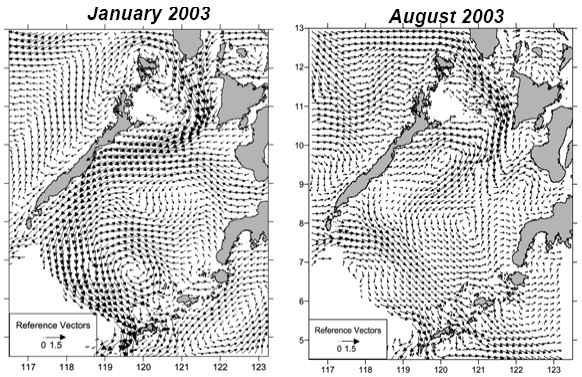

Figure 5. Current patterns in Sulu Sea derived from the Pacific HYCOM (http://hycom.rsmas.miami.edu/) used to force dispersal model for the entire basin (Sulu-Sulawesi Seascape).

These matching and mismatching of spatial patterns of distributions of the various life stages of benthic reef-associated fishes in Sulu Sea are influenced by two major environmental factors. One is the local water circulation pattern (Sale et al., 1984, 2005, Bode et al., 2006) at the different corridors in the Sulu Seascape, which potentially disperses egg and larvae within and between corridors, implicating shifts in connectivity potential of fish populations. There is a concordance on the diversity of juvenile fish species in areas of high entrainment (Carassou and Ponton, 2007) and with adult fish species. The second major factor is disturbance and/or stresses such as over-fishing and habitat degradation. Mortality in fish populations at varying stages of their life history will therefore reduce the connectivity potential in a range of spatial scales in the Sulu Sea (e.g. Sale et al., 1984, Sale and Kritzer, 2003).

Conclusions

Abundances of adult and juvenile fishes were high in Tubbataha and Cagayancillo suggesting that recruitment, survivorship and growth rates in these areas are also high which may serve both as a source and as a sink.

Adult fish had clearer spatial pattern than juveniles. ANOSIM revealed significant differences vis-à-vis their location among sites indicating site as a factor affecting fish community structure. However, juvenile had clearer patterns in terms of temporal pattern than former.

Spatial distribution patterns were influenced by (a) local water circulation patterns which potentially influence the connectivity of fish populations and (b) disturbance and/or stresses (i.e., over-fishing and habitat degradation) which increase the mortality of fish populations at varying life stages and therefore affect their survivorship and reproductive outputs at each corridor.

Results from this study fill critical gaps in developing scenarios on connectivity and their implications to management and biodiversity conservation. These areas would be important in the design of MPA networks and in the improvement of critical management gaps such as reducing threats through integrated coastal management, enhancing survivorship, strengthening enforcement and education about reducing threats and disturbances.

Size spectra analysis as a tool to examine management effectiveness of marine protected areas

T. Kartawijaya, R.L. Ardiwijaya, S.T. Pardede, A. Mukminin, S. Campbell

Wildlife Conservation Society – Indonesia Marine Program, Jalan Burangrang 18, Bogor 16151, Indonesia

Abstract. Following extensive community consultation and resource assessments the allowable uses within Karimunjawa National Park (KNP), Indonesia, were re-zoned in 2005. The aim was to improve the health of coral reefs and increase the biomass of reef fish. We evaluated the effectiveness of zoning by comparing the abundance and size of reef fishes among no-take zones (entry prohibited), no-take zones (entry permitted) and fishing zones. The census included all reef fish species and each fish was placed into size class categories of 5cm increments from 0 to 40+ cm. Biomass was calculated using established weight-and-length relationships. The biomass of large fishes was generally higher in no take zones (mean ± S E: 536 ± 113 kg ha^{-1}) than in no-take zones (entry permitted) (353 ± 63 kg ha^{-1}) and fishing zones (301 ± 39 kg ha^{-1}), although the effect was not significant. Size spectra analyses showed that reef fish structure did vary among management zones with reef fishes in size class of 15-20cm and 35-40cm most abundant in the no-take zone (entry prohibited). Fish in the no-take zone (entry prohibited) were mostly of target species, including fusiliers, emperors, snappers and groupers. In contrast, small (5-10cm) non-target species, mainly wrasses and cardinal fishes, were more abundant in the fishing zones. The higher biomass of large sized fishes inside no-take zones (entry prohibited) is most likely because fishing pressure has been reduced. Although enforcement of fishing regulations inside the park remains inadequate, the results suggest that fishing restrictions are receiving support among fishers and if support continues fish stocks in all zones may increase.

Key words : Karimunjawa National Park, effectiveness management, size spectra, biomass.

Introduction

Karimunjawa National Park is one of eight national marine protected areas in Indonesia and is situated 120 km north of Semarang, Central Java, Indonesia (Fig. 1). Based on Indonesia law No. 5/1990 regarding the conservation of natural resources and ecosystems, the national park is managed by a zoning system. A rezoning process was conducted from 2003 to 2005 as part of an effort to design an effective management system by the National Park Authority with the aim of improving health of coral reefs and to increase the biomass of reef fish. We evaluated the effectiveness of zoning by comparing the abundance and size of reef fishes among no-take zones (entry prohibited), no-take zones (entry permitted), and fishing zones.

Material and Methods

The fish community was sampled using visual census methods recording all fish to species level, except for gobies (Gobiidae), blennies (Bleniidae), and triplefins (Tripterygidae). Fish biomass was calculated using total length (cm) of fish and converted into weight (kg) using length-weight relationships (Froese and Pauly 2000).

Information on fishing grounds, number of fishers, and type of gears were collected during interviews with fishers in Karimunjawa National Park between March 2005 and February 2006.

Two-way ANOVA were used to test for differences in fish biomass between management zones and size classes and between, management zones and trophic groups. Data were tested for normality and log transformed prior to analysis.

Results and Discussion

Reef fish biomass in no take zones (entry prohibited) was significantly higher than in no take zones (entry permitted) and fishing zones. Size structure also differed between zones with high biomass of fish in size classes from 15 cm to 40 cm in no take zone (entry prohibited) than the other 2 zones. (Fig. 2).

Reef fishes in the no take zone (entry prohibited) and no take zone (entry permitted) had higher size

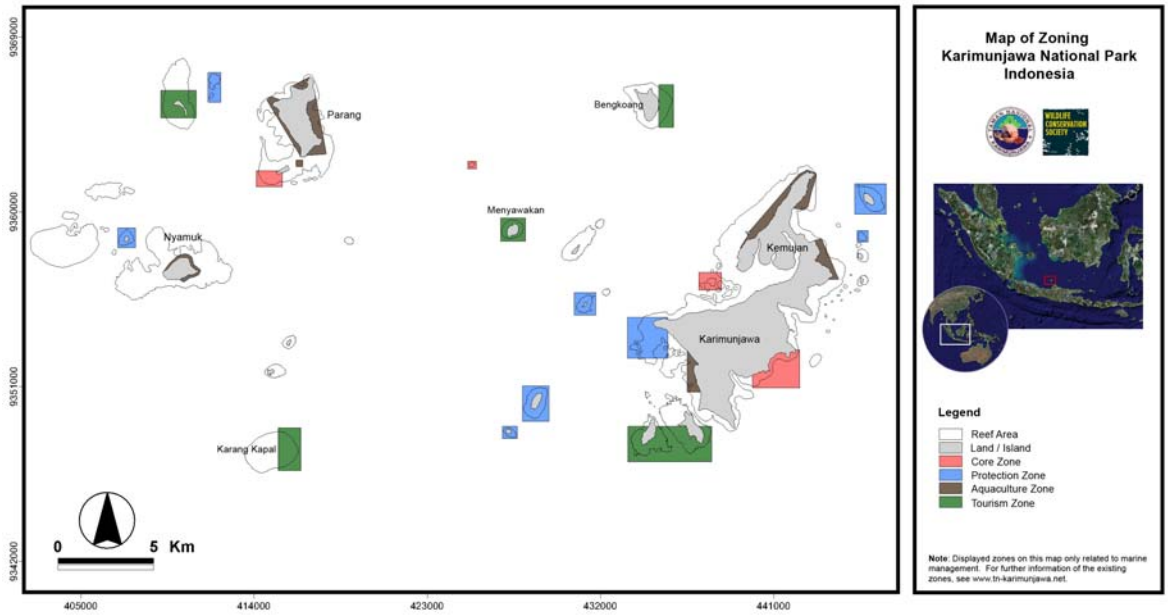

Figure 1. Map of Karimunjawa National Park, Central Java Indonesia.

classes, from 15-20 cm to >40 cm. Most fish in these size classes were fusiliers (Caesionidae), snappers (Lutjanidae), groupers (Serranidae), and emperor (Lethrinidae), which are target species for fisheries in Karimunjawa. The majority of fishes in fishing zones size class consisted of wrasses (Labridae) and cardinal fishes (Apogonidae, Fig. 3).

Management Zones x Trophic Groups	20	0.803	1.564	0.064
Error	21	0.514		

Fishing Intensity

The numbers of fishing trips in each zone revealed that the fishing pressure in the no take zone (entry prohibited) and no take zone (entry permitted) were lower than in the fishing zone (Figure 5).

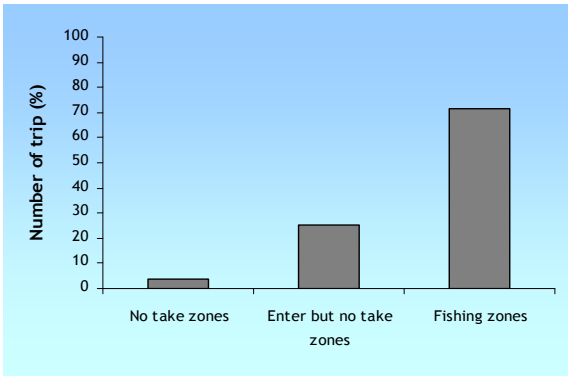

Figure 5. Fishing pressure in 3 management zones.

Conclusions

- Reef fish biomass in the no take zones (entry prohibited) was higher than in no take zones (entry permitted) and the fishing zones.
- Medium and large size classes of target species were most abundant in the no-take zone (entry prohibited).
- Reef fish condition will be improved if all stakeholders and fishers have awareness of sustainable fisheries practices to achieve better management in Karimunjawa National Park.

Acknowledgement

The authors are grateful to the financial contribution of the David and Lucille Packard Foundation, the logistical support provided by staff of the Karimunjawa National Park Authority. The collection of fisheries data would not have been possible without the kind co-operation of local fishing communities in Karimunjawa. Ripanto collected fisheries data.

The Relevance of Traditional Ecological Knowledge for Modern Management of Coral Reef Fisheries in Melanesia

Abstract - Traditional ecological knowledge (TEK) has received great attention in respect to coral reef associated fisheries as a way to adapt modern management strategies to local environmental and cultural conditions. We analysed the social and cultural roles of TEK for resource management in traditional Melanesian communities in New Caledonia. A multidisciplinary survey of customary marine tenure and fishing regulations on Ouvéa, a raised limestone island in New Caledonia, was carried out in 2006. Informants from the main chiefdoms and clans were questioned about past and present fishing activities, maritime territory rights, taboo areas and place names, customary authority, socio-cultural practices and belief related to marine resources, and vernacular knowledge and taxonomy of marine organisms. Results showed that customary fishing rules were primarily related to cultural events and social organization rather than to ecological patterns or economic interests. The relationships between TEK, population needs and uses of the environment were still strong, but have changed since the 1860s. An unquantifiable loss of indigenous knowledge has also occurred. Nowadays, to satisfy food and economic needs, modern users often abandon TEK and behave in relation to their own individual economic perceptions and needs. Better consideration of social and cultural aspects in resource management issues may therefore directly help to increase awareness of resource depletion and biodiversity loss as a basis for achieving long-term ecosystem and economic sustainability in Melanesian islands.

Key words: coral reef, fisheries management, traditional ecological knowledge, New Caledonia, South Pacific

Introduction

Marine traditional ecological knowledge (TEK) is part of the larger body of indigenous knowledge. It is defined as a complex of knowledge of sea (i.e. reefs, lagoons and target species), livelihood activities (fishing techniques and practices, management rules), and related magic, beliefs and legends of social and cultural values (Berkes and Folke 1998). This knowledge constitutes a user-based accumulation of experience and observations that has been improved and transmitted orally through generations (Ruddle 1993; Turner and Berkes 2006a).

A large part of the literature about marine TEK has addressed the local knowledge of the environment or the taxonomy, the biology and the ecology of marine organisms (Aswani and Hamilton 2004; Lauer and Aswani 2008; Fraser et al.. 2006) as well as the sustainability of indigenous practices (Johannes 2002; Lobes and Berkes 2004). Zooarchaeological evidence has also shown that not all practices were conservative and that early human settlement in many remote Oceanic islands led to sharp depletions of virgin terrestrial and marine resources, such as birds and shellfishes (Kirch and Hunt 1997; Steadman 1995). One the other hand, there is increasing evidence that TEK can improve the understanding of resource use patterns and the monitoring and the adaptive management of coastal fisheries (Danielsen et al. 2005; Turner and Berkes 2006b). This case study of Ouvéa Island (New Caledonia), a raised limestone island with Melanesian and Polynesian communities, is an empirical evaluation of the relationships between TEK and the modern management of coral reef fisheries. Here we provide an interpretation of the social and cultural significance of TEK for indigenous populations and the roles that it could play in the sustainability of contemporary fisheries in Melanesia.

Materiel and methods

The functions of TEK within the Melanesian socio-political organization

In the traditional Melanesian cultural system, intrinsic interactions between humans and nature gave TEK a key role in regulating subsistence fisheries (Leblic 1989): the fishing system was driven by a dynamic linkage between community needs, TEK and uses

(Fig. 1a). Traditional socio-political organization resulted in a complex management system of fishing activities that were broadly controlled by TEK, but did not fully succeed in preventing overexploitation. The co-evolution of TEK with the surrounding environment was necessary to respond to both gradual and rapid change and to meet basic food and other subsistence needs. These needs were also linked to an array of social and cultural factors that determined formal and informal rules, codes of conduct, stories, and local taxonomies, among others. Particularly important factors related to TEK included the legitimacy of knowledge holders and territory owners, competition for leadership, the differentiation of the socio-political roles among people, and clan identity within the Melanesian society (Bensa 1995; Guiart 1992).

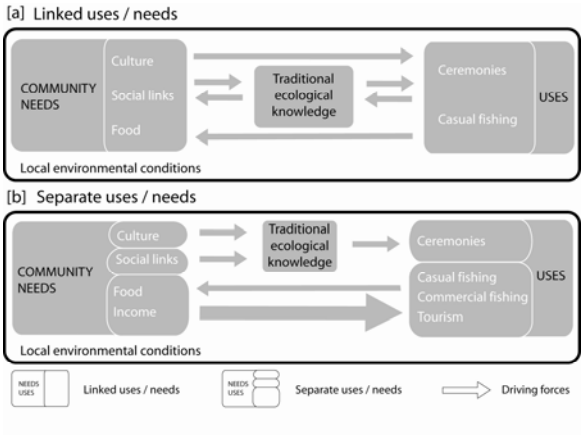

Figure 1. Relationships between traditional ecological knowledge, needs, and uses of marine resources in the traditional Melanesian cultural system [a] and in modern fisheries [b].

These roles were usually linked to the skills and totems of many successive migrants from different origins. As in many other Pacific islands, over the last few centuries, several waves of settlement by groups of both Melanesian and Polynesian origin are documented for Ouvéa since the first occupants arrived from Vanuatu or the Salomon Islands 4000 years ago (Guiart 1952; Sand 1998). These include settlers from the nearby islands of Lifou and Grande Terre (the main island of New Caledonia) and from Polynesia (Samoa, Wallis or West Uvea, and Tonga). The latter Polynesian groups settled in the northern and southern parts of the island in the 18th century. The body of Ouvéa TEK has, thus, been shaped by the importation, aggregation, synthesis and transformation of different sources of knowledge, including the Melanesian (*Iaai*) and Polynesian (*Faga Uvea*) languages or techniques (e.g, the distinctive construction of wooden canoes or sailing boats).

Study site and survey design

Ouvéa is a crescent-shaped raised limestone atoll-like island with a total land area of about 50 km^2, which extends some 51 km from the northwest to the southwest and is about 7 km wide at its widest point (Fig. 2). The island encircles a large 836 km^2 lagoon with depths up to 25 m deep that is enclosed by barrier reefs and islets along its northern and the southern shores. The inner lagoon coast is lined with an almost continuous 30 km-long white sand beach, whereas the outer Ocean side coast has raised limestone terraces and fringing coral reefs along most of its extent.

The local population (4400 inhabitants 97 % of whom are Melanesian) is distributed in 20 traditional tribes, who have *de facto* collective control over Ouvéa waters. This customary system is contradictory to New Caledonia law that stipulates that lagoon and shoreline are public property and thus open to all.

Available quantitative data on fish resources and catches are included in the analysis. The annual catch of fish was estimated to be 200 t and was mainly composed of Lethrinidae and Serranidae (Léopold et al.. 2004). More than 90 % of this catch was harvested in the lagoon area (about 95 % of the fishing grounds). About 15 % was sold on the local market; commercial fish exports were very low. This low fishing pressure has markedly preserved the fish biomass of the island (Kulbicki et al. 1995).

Using open-ended and qualitative interviews, we conducted a multidisciplinary survey in the northern and the southern Districts in 2006 to explore the traditional relationships between Kanak residents and their reefs and lagoon. The methodology consisted of interviews of all customary leaders of the different clans and chiefdoms of both Districts, who were questioned about social and cultural practises and stories related to the marine environment, customary authorities, local knowledge on marine life, fishing activities, territory rights, taboo areas and place names. High resolution aerial photography was used to localize sites and related data when appropriate.

Results

Fifty-one interviews of knowledgeable people were completed. We found that resident fishers have open access to the entire lagoon area, whereas outsiders coming from neighbouring islands for recreational activities or professional fishing are vigorously prosecuted.

All emerged areas and adjacent reefs are owned by the first settlers who have sometimes granted their guardianship to another social group. Interestingly, there are no local place names or traditional uses mentioned for the lagoon area, which suggests that there has been little need to depend on these

resources and areas for traditional purposes. Well-defined clan or tribal fishing grounds or territories are defined in reef and lagoon areas of the Northern and Southern Pleiads (about 40 km^2), and along the windward fringing reef (about 4 km^2) (Fig. 3). These are identified by vernacular place names of reefs, coral heads, passes, beaches, cliffs, etc. that remind people of the itineraries and myths of clans' ancestors. Species and gear restrictions are applied in a number of taboo sites where stories have recorded mythic relationships between people and marine animals (sharks, the humphead wrasse *Cheilinus undulatus*, morays, sea turtles, etc.). Specific customary rules also apply to sea turtles and large jacks (e.g. *Caranx ignobilis*) that are killed and shared according to ritual ceremonies.

No no-take zones were recorded but two types of reserved areas are present (Fig. 3):

i) Four marine areas are controlled as customary temporary reserves: 1) Lékine-Faiava reserve in the east, which extends into a shallow lagoon marked by strong tidal influence; 2) Mouli reserve in the southeast and 3) Teuta reserve located inside the lagoon alongside a coral cliff and a sandy beach respectively; and 4) Ognat reserve, which extends over the windward fringing reef. Their surface areas range between 0.2 and 1.5 km² and total about 2.5 km². Openings of the reserves to fishing are not implemented for a defined period but rather depend on social agendas and resource availability that may not be predictable. Interestingly, the protection status inside all taboo areas encompasses the physical environment and protects the reef habitats from direct human disturbances (e.g. wharf building).

Castnet and handline subsistence fishing is allowed in the four taboo sites because, according to local perceptions, such activities do not impact as negatively on fish resources as more effective methods (e.g. spearfishing, poisoning, and gillnetting). Significant fishing effort is only deployed during collective fishing trips to celebrate major social events (e.g. marriages, funerals, church ceremonies, etc.), which occur once to several times a year. Successful fishing is associated with abundant catches over a period of only a few hours, during when numerous fishers use nets hundreds of meters in length. Schooling species, such as the Indian mackerel (*Rastrelliger kanagurta*) and mullets (Mugilidae) are specifically targeted in Mouli and Teuta reserves respectively, whereas mainly reef species (Acanthuridae, Scaridae, Siganidae, etc.) are targeted in the two other taboo areas. The catches occasionally exceed a ton per day.

The main reason for the establishment of temporary reserves is to maximize catches during collective fishing trips. However this utilitarian pursuit for food should not hide its fundamental social and cultural importance. Such events remind fishers of their distinct customary roles based on traditional sociopolitical organization and their TEK. Such fishing activities are deeply embedded in social arenas where gifts of fish are used to strengthen and legitimize the hierarchical structure of the chiefdoms. Consequently traditional fishing rules may not survive the weakening of the social structure and the loss of TEK. For instance the ban on mullet net fishing in the Teuta taboo area is linked to the tribe's allegiance to the Weneki chiefdom, which is no longer enforced since the custodians have contested the authority of the land and marine resource owners on the site. As a result, the mullet fishery was recently opened to commercial harvest.

Similar clan-based political strategies and territory rights drive other collective fishing events on the windward fringing reef of the main island. The same net fishing techniques are used to target reef species, particularly the forktail rabbitfish *Siganus argenteus*.

ii) The Kanak of Mouli and Saint-Joseph Districts are historically and culturally attached to the Southern and Northern Pleiads respectively, where there are traditional plantations on all islets, and two of them (namely Bagaat and Unyee) were inhabited until the early 1900s. The nearby reefs, passes, and lagoons are also reserved for the collective benefit of the local residents as a food source though fishing rights are not exclusive. Fishers from Fayaoue District are allowed to use trawling and bottom lines in the areas for subsistence and commercial activities, and spear guns once they have formally gained the land owners' or the custodians' permission.

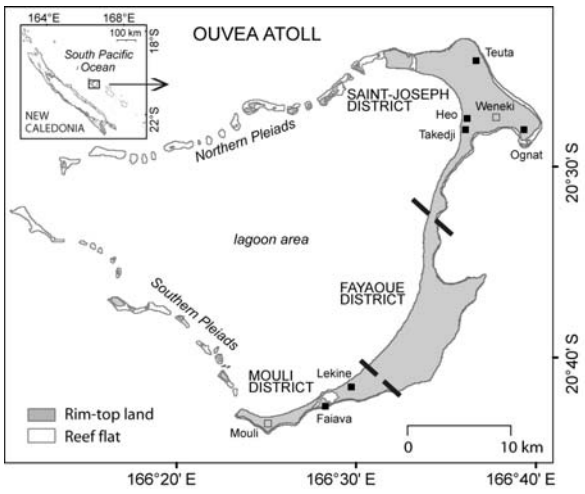

Figure 2. Ouvéa atoll (New Caledonia, South Pacific). Squares: Melanesian tribes in the survey area (Mouli and Saint-Joseph Districts). Unfilled squared: main chiefdom of both Districts.

Spear fishing was recently banned in the southern coastal waters to prevent shark attacks near the main tribal villages. This is the only locally-based decision that is not linked to Ouvéa social and cultural organization.

Discussion

Our results show that on Ouvéa fishers rarely used TEK and referred to recent experiences of the use of modern fishing gear when looking for food and income. European settlement and economic development have indeed changed the relationships between Melanesian people and their marine environment due to technical, geographical, socio-political and educational developments since the 1860s (Izoulet 2005). Similar trends occur in traditional societies in other Pacific Islands and countries (Murray et al.. 2006; Wittersheim 2006; Sillitoe 2000; Johannes 1978). On Ouvéa boats with outboard engines have given fishers access to new and more-distant fishing grounds inside the lagoon area rather than having to depend nearby surrounding fringing reefs and beaches off the main island and the Pleiads (Léopold et al. 2004), where traditional territories are located. More efficient fishing gear (e.g. nylon nets, spear guns) has also made fishing less uncertain, even for inexperienced fishers. More globally, progressive changes in population needs have finally marginalized fisheries-related TEK (Fig. 1b).

We found that TEK still has an important role in the Melanesian sociopolitical structures on Ouvéa. It now mainly addresses the social and cultural need to maintain traditional links between people, clans and chiefdoms rather than to protect the fishing economy or the environment *per se* (Fig. 1b). It is therefore a major part of the Kanak cultural heritage, as are marine resources and landscapes. Importantly sociocultural needs seem to be the driving force behind almost all existing local fishing regulations. Specific rules have been designed to protect coral reef habitats in many sites of social and cultural importance, which have in turn mitigated fishing pressure on certain resources.

This case study suggests that cultural considerations can contribute to the design of management projects: they may be the main objectives of local fishing rules and the primary incentive for participative initiatives and modern management of fisheries. Revitalizing TEK would thus be central to an efficient culture-based strategy for fishery management. The strengthening of TEK and its social and cultural underpinnings may help to lever up ecological awareness because of its significance for local people and their customary values (Berkes 2008). This would indirectly increase the non-use and conservation value of the marine ecosystem of Ouvéa and help to balance economic and conservation interests in the future. Following various authors, our observations confirm that resource management in Oceania should rely on local socioeconomic conditions (Cinner 2007; Cinner et al. 2005) and customary marine tenure systems (Aswani 2005) and social structures (Horowitz 2008; Leblic 2008).

There may also be an important role for TEK and traditional values to play in fisheries management at scales beyond the community level on Ouvéa (Berkes 2006). Whereas, in the past, passive conservation of Ouvéa marine resources was ensured by the low human population density, limited commercialization of marine resources, and simple fishing technology, these are now changing. As a result fishers are now increasingly targeting the lagoon area that had not been traditionally managed. Such activities have not been controlled by public authorities because of a lack of enforcement of official regulations. Thus up-scaled measures are now required to regulate new emerging uses threats to marine resources (e.g. cruise ship tourism, developing commercial small-scale fisheries, and ciguatera poisoning), which could complement the existing small locally-managed areas. Such up-scaling of management and the application of TEK would require a change in governance to involve customary as well as public authorities in a collaborative management framework (Cinner and Aswani 2007). In this context, the addition of Ouvéa to the UNESCO World Heritage List in July 2008 provides a unique opportunity to use TEK as a tool for an innovative management of coral reef fisheries and ecosystems at the island scale. It would also engage traditional leadership in the linked conservation of the island's natural and cultural heritage. In this sense this nomination has formally and internationally recognized the strong linkage between culture and fisheries sustainability in Melanesia.

Acknowledgement

This study was funded by the CRISP programme (Coral Reef Initiative for the South Pacific – www.crisponline.net) as part of the collaboration between the French Institute of Research for Development (IRD) and The University of the South Pacific. The authors want to particularly thank Joseph Baly for his help in conducting the interviews of customary leaders.

Managing fishing gear to encourage ecosystem-based management of coral reefs fisheries

Abstract. We present fisheries landing data from two tropical countries, Papua New Guinea (PNG) and Kenya, and show that each gear type causes a unique and consistent partitioning of the species and functional groups it targets. Partitioning by gear can be used to influence ecological processes and biodiversity on coral reefs and to respond to disturbances such as coral bleaching. Hook and line capture a higher proportion of top carnivores and piscivores and target species with low susceptibility to coral bleaching. Traps, drag nets, and spearguns capture mostly herbivores and omnivores and target the highest proportion and number of fish species that are moderately susceptible to the effects of coral bleaching. We argue that the use of specific gears can be actively managed to encourage the recovery of select functional groups and adaptively manage for reducing high erect algae cover and sea urchin dominance, increasing coral cover, and reducing detrimental effects of coral bleaching. We present a simulation and conceptual model that describes the effects of gear and effort on fisheries yields and suggest a mechanism for practically implementing this model. Spearguns are predicted to have the highest diversity and yields of catch, but can also result in decline in herbivorous fishes, which has serious consequences for recovery and resilience of the ecosystem. Further understanding of fishing gear effects on specific fish functional groups at a broader selection of reef locations will be valuable in developing adaptive gear-based management in a changing climate.

Key words: Climate change, coral reef model, ecological effects, fisheries yields, herbivory, trophic cascades

Introduction

Coral reef ecosystems are complex and therefore difficult to manage from a holistic systems approach when social conditions do not facilitate the use of large fisheries closures. Suggestions for management based on an understanding of coral reef ecology are a useful first step but their implementation often depends on complex and challenging socioeconomic considerations (McClanahan et al. 2008). Finding appropriate ways to implement management measures that can be adopted by fishing cultures with resultant desired ecological consequences is perhaps one of the greatest challenges for ecosystem-based management of coral reefs. Management of fishing gear can potentially achieve this goal in areas where fisheries closures are impracticable. Gears are selective in their catch and are a management option mostly accepted by fishers and managers (McClanahan et al. 2005).

The impact of climate change and coral mortality on reef ecology, fish, and fisheries are multiple and complex. Hence, there is a need to evaluate fishing and gear-use scenarios with ecological models based on a holistic view of the ecosystem and existing field data. These models can assist researchers in testing and predicting outcomes and encourage an adaptive management program for coral reef ecosystems. Current understanding of coral reef fisheries has focused on the potential effects of the loss of grazers and invertebrate-eating carnivores (McClanahan 2006). Many investigators believe that the protection of coral reef grazers will be important for maintaining the recovery of coral reefs after disturbances (Hughes et al. 2003; Bellwood et al. 2004; Mumby et al. 2006). Additionally, coral-eating invertebrates, such as Crown-of-Thorns starfish and algae

grazing sea urchins can become pests and compromise ecological processes and recovery potential in some reef environments (McClanahan et al. 2002; Dulvy et al. 2004). These aspects of management were previously examined in an ecosystem model assuming choice of functional groups by fishers (McClanahan 1995).

The objective of the present paper is to examine the potential benefits of gear management strategies to maintain selected ecological processes and enhance reef recovery after coral depleting disturbances. We analyze the composition of fish catches in artisanal fisheries in two countries with different gear uses and levels of fishing effort and evaluate the effects of gear–specific fishing intensity on functional groups of reef fishes.

Materials and methods

The study examines fishing gear and catches in two countries that represent a low to moderate level of fishing (Papua New Guinea; PNG), and moderate to high level of fishing, (Kenya; Cinner and McClanahan 2006; McClanahan et al. 2008). We evaluate the species and functional group selectivity of gear used in artisanal fisheries (net, speargun, beach seine, line and trap) in these two countries and use these data to calibrate an ecosystem simulation model. Model simulations are then used to forecast catch and stock status of selected functional groups under increasing fishing pressure for the different gears.

Field studies of catch by gear

Catch data are based on six fishing sites in PNG (Cinner and McClanahan 2006) and ten fish landing sites in Kenya (McClanahan et al. 2008). Landing sites were selected to represent a wide range of social, economic, and demographic conditions. The fisheries were typical tropical artisanal fisheries where catch was derived from shallow-water coral reef and seagrass ecosystems. Analyses of catch data are based on 4205 and 2154 fish specimens from Kenya and PNG, respectively.

Methods to sample fish catch in the two countries differed slightly. In both countries we opportunistically examined fish landings at all times of the day and night by approaching and asking permission from fishers as they returned from fishing activities and the whole catch was measured whether the catch was for market or home use. Abundance and taxonomic composition were recorded to species level (Lieske and Myers 1994; Randall et al. 1997). In PNG, we photographed the fish using the methods of Cinner and McClanahan (2006) and recorded the gear used to capture each fish. When multiple gears were used in a single trip, we separated the catch by gear type. In Kenya, catches were identified, counted, and measured to the nearest centimeter using a fixed marker rule on a flat board. Where possible the entire catch was sampled, alternatively a sub sample was measured, ensuring that each gear used at each site was adequately sampled and each species landed was recorded.

Although a variety of fishing gears and techniques were used throughout PNG, three main gear types were widespread and used in sufficient numbers to be useful for management and comparison; line fishing, gill nets, and spearguns. In Kenya, these three gears were also commonly used along with beach seines and traps. The infrequent use of other fishing methods (weirs, poisons, bombs, and derris root) did not allow for sufficient data to make comparisons.

Catch and gear analyses

We used expert opinion to group species into the following functional groups, based on their diet: piscivore, macro piscivore-invertivore, plankivores, macro and micro invertivores, grazer (micro-turfs), macrograzers (seagrass and large erect algae), scraper/excavator (parrotfish that remove coralline algae and calcium carbonate while grazing), and detritivores. We also classified species particularly important for ecological processes as a "key-species", i.e. batfish and red-lined triggerfish (McClanahan 2000, Bellwood et al. 2006). We used ordination plots generated by correspondence analyses to examine how nation and gear were related to the above functional guilds and species.

Simulation model development

A coral reef computer-based simulation model was developed to specifically run scenarios for fisheries management using the above gear types. This model, which has been given the acronym CAFFEE (Coral-Algae-Fish-Fisheries Ecosystem Energetics), is a system-dynamic model of a coral reef ecosystem based on the transfer of energy implicit in interactions between functional groups. The model is an expansion and improvement on a previous model (McClanahan 1995).

CAFFEE was developed in STELLA to represent a conceptualized reef food-web that integrates 17 functionally distinct groups across four trophic levels, including 6 primary producers, 8 primary consumers, 2 secondary consumers and 1 tertiary

consumer (Fig. 1). Interactions between functional groups were modeled using an energy-based approach that considered metabolism and biological processes (production, consumption, assimilation, respiration, excretion), as well as ecological factors such as resource competition, density-dependent consumption, and group-specific rates of capture by different fisheries. A detritus-cycle including benthic and pelagic DOM and POM was also incorporated. Calibration used parameters obtained from the literature or derived from datasets provided by collaborating scientists (a full list of references is available on request). A fuller presentation of the model's equations and calibration is forthcoming.

Simulations in the absence of fishing effort ('pre-fisheries' conditions) were allowed to run until a steady state was achieved (i.e. until the values of all stock variables had less than 0.1% of annual variation). The standing stock of each functional group at this stage was taken to be the 'pre-fisheries stock' and these values were used as initial or steady-state stock values (30 to 50 years of simulation) for determining the effect of all further fisheries simulations.

Steady-state stocks of functional groups were compared at different levels of fishing effort with 'pre-fisheries stocks' for different fisheries in order to identify gear-based management strategies likely to enhance reef recovery after disturbance. The model's program increases the catch rates of different gear types at 1 fisher per km^2 intervals and the effect on the stocks on key functional groups were taken and plotted. Gear and catch data from the PNG and Kenya landing sites were used to calibrate the fisheries parameters of the model and here we focus on the effects of effort and gear use on total yields and grazer abundance.

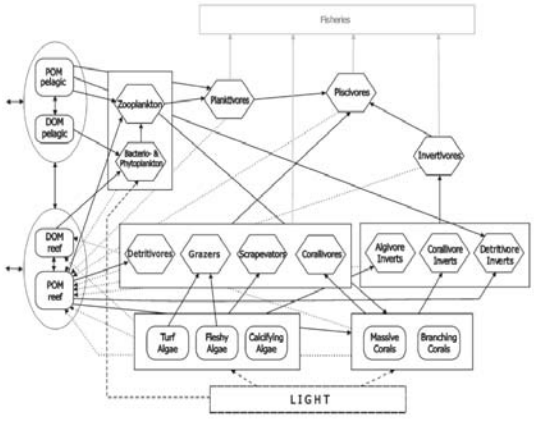

Figure 1. Systems diagram showing the main components and flows of the coral reef ecosystem model used in the gear-use simulation experiments.

Results

Gears were strongly associated with functional groups in both countries (Fig. 2). PNG spearguns caught mostly (micro) grazers, scraper/excavators, detritivores, and planktivores. Kenyan spears, traps, and beach seines caught more grazers (i.e. browsers) and invertivores. Hook and line in both Kenya and PNG captured more carnivores but Kenyan catches had fewer planktivores. Set or gill nets predominantly caught carnivores. Nets in PNG caught piscivores and macro-invertivores, whereas Kenyan nets caught more micro-invertivores and some grazers.

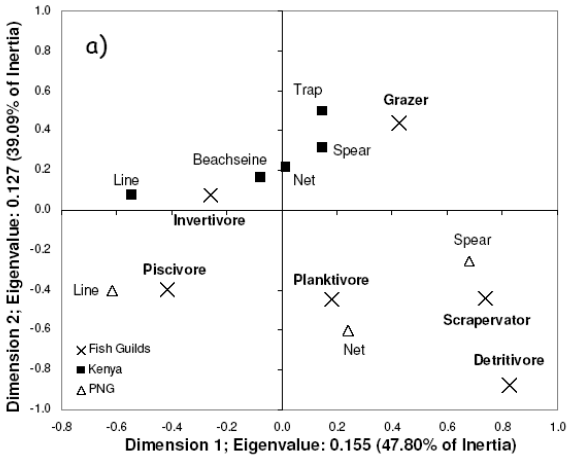

Figure 2. Correspondence analysis plot showing the relationships between functional group catch by gears in the two countries. Scrapervator = scraping and excavating parrotfish.

Model simulations using the calibration for the PNG catch produced three distinct responses for catches by the gear types - spears, nets, and hook-and-line (Fig. 3). Spears produced the highest yield but it was also associated with a collapse in the fisheries beyond the maximum catch, which for this simulation calibration was found at 12 fishers km^{-2}. Nets produced the second highest yields and above 25 fishers km^{-2} did not increase the total yield. Hook and line produced the lowest total yields and declined above 25 km^{-2} for increasing fishing effort, suggesting a constant diminishing catch per fisher. Model outputs calibrated for all gears and pooling all grazers together into a single functional group indicate that spearguns, traps, Kenyan gill nets, and beach seines will reduce grazers to extinction at moderate levels of fishing effort while grazer fish stocks will be able to

sustain greater fishing pressure by lines and the nets used in PNG (Fig. 4).

Discussion

Field data on fish catches by gear in the two countries indicates strong associations between the functional groups of caught fish and types of gear used with some differences in the two nations. We expected the effect of "nation" due to the different levels of fishing intensity and history in the two countries. Kenya has higher numbers of fisher and fishing intensity than PNG. With regard to fisheries yield, the main difference between Kenya and PNG was the high amount of grazers, particularly macro-grazers, caught by spearguns, beach seines, and set nets in Kenya. Many of these macro-grazers feed in and on seagrass and erect algae, and national differences are likely a result of greater use of seagrass ecosystems and greater fishing pressure in Kenya (McClanahan et al. 2008).

Spearguns largely catch herbivores of various kinds in both countries, and a considerably high diversity of other species, as demonstrated by catch-biodiversity studies (McClanahan and Cinner 2008). This high diversity of catch is likely to explain the rapid decline in catch at high levels of effort found in speargun simulation models. The high diversity of catch allows more resources to be utilized but the ultimate consequence of this versatility is a potential for total fisheries collapse at high levels of fishing effort. Fisheries involving gear with low catches of grazers did not collapse but the catch per fisher is extremely low at high levels of effort for PNG nets and hook and line. It is likely that fishers will switch to more effective gear as yields drop, and this may lead to greater use of beach seines and spearguns, with associated losses of grazers (Pauly et al. 1989; McClanahan et al. 2008). Catching fish higher in the food web may not result in the loss of grazers and may help conserve corals, but it is also associated with lower yields. These yields are, however, more stable and less likely to collapse. Lower, yet sustainable, yields are indicative of the types of trade offs required in managing fisheries.

It would appear that gears effective at catching reef grazers should be avoided in order to prevent their population collapse and possible degradation of reefs associated with low grazing. This has not occurred in Kenyan reefs because grazing sea urchins have largely occupied the niche of grazing fish (McClanahan 2008). The catch of reef grazers has also been stable in Kenya, as most catch is now derived from seagrass ecosystems that appear less likely (or possibly slower) to collapse or to become dominated by sea urchins (Heck and Valentine 2007; McClanahan et al. 2008). Where overfishing effects are not buffered by seagrass and sea urchins, we may expect to see degradation of coral reef ecosystems and collapses of fish populations at lower levels of effort, especially where the most effective or destructive gear are not controlled. We

suggest that knowledge of fishing gear effects can be used to develop a conceptual basis for adaptive ecosystem-based coral reef management. Knowledge of functional groups and their effects on reef processes can be utilized to develop a feedback between the state of the reef ecosystem and choices of gear use (McClanahan and Cinner 2008).

Indications of Recruitment Enhancement in the Sea Urchin *Tripneustes gratilla* Due to Stock Restoration Efforts

M. A. Juinio-Meñez[1] , D. Pastor[1] and H. G. Bangi[2]
[1]Marine Science Institute, College of Science, University of the Philippines, Diliman, Quezon City 110
[2]College of Aquatic Sciences and Applied Technology, Mariano Marcos State University, Currimao 2903, Ilocos Norte, Philippines

Abstract Field monitoring activities were conducted in various sites in five provinces in northwestern Philippines in 2004-2007 to assess the impacts of restocking and grow-out culture of hatchery-reared *Tripneustes gratilla* juveniles. High incidences of recruits (<4.0 cm test diameter) were noted during the last quarter of 2005 through the first quarter of 2006. Very high densities (up to 460 individuals 100 m^{-2}) were recorded in Lucero, Bolinao, Pangasinan, which is the site for sea urchin broodstock and grow-out cages. Eighty percent of the total density was comprised of recruits of the year. In Sinait, Ilocos Sur, total density and incidence of recruits were significantly higher (up to 67 individuals 100 m^{-2}) than two sites in Ilocos Norte where there was no grow-out culture of sea urchins. In Poro Pt., La Union sea urchins increased after the initiation of grow-out culture activities in 2005 and peaked at 14 individuals 100 m^{-2} in 2007. The positive correlation in the density of recruits and adults in four sites in Bolinao together with the higher densities and incidence of recruits in different grow-out areas concur with the hypothesis that the aggregation of adults in grow-out culture areas enhanced benthic recruitment.

Keywords: recruitment, sea urchins, grow-out culture, stock restoration

Introduction

The reef flats of the coastal municipality of Bolinao, Pangasinan were a prime sea urchin fishing area for *Tripneustes gratilla* in the 1970s through the late 1980s. Unregulated harvesting precipitated in the collapse of the fishery in 1992 (Juinio-Meñez et al. 1998). Hatchery culture was initiated in 1994 and juvenile production was scaled-up by 1996 for restocking to enhance the recovery of the sea urchin fishery in Bolinao. To optimize survivorship of the limited numbers of hatchery-reared juveniles to adulthood, community-based grow-out culture was developed as an adaptive resource management tool to address both ecological and socio-economic considerations while rebuilding the spawning population (Juinio-Meñez et al. 1998). From 2000 to 2006, about 50,000 juveniles were used annually for restocking in selected protected areas and grow-out culture in the Bolinao area. After the Bolinao fishery collapsed in 1992, no natural recruitment was evident until 1999 when a few juveniles were first reported again. During the last quarter of 2004, a strong recruitment pulse was noted together with the increase in the landed catch of collectors, indicating recovery of the natural population in Bolinao. This was further boosted by an even stronger recruitment during the last quarter of 2005 through the first half of 2006 (Juinio-Meñez et al. 2008).

Sea urchin grow-out culture in sea cages was promoted and expanded in the provinces of Ilocos and La Union using wild juveniles to reestablish viable spawning populations and provide a supplemental source of livelihood for fishers in collaboration with fisher's organizations, local government units, regional state universities and the Bureau of Fisheries and Aquatic Resources (BFAR). Among these sites were Sinait, Ilocos Sur and Poro Point, La Union. In Sinait, Ilocos Sur, three to six cages with 500-700 sea urchins per cage were maintained near a marine protected area since 2004. In Poro Point, La Union, a total of 30,000 juveniles (i.e. 60 cages stocked at 500 urchins per cage) were used for the grow-out cages starting December 2005.

Methodology

Data on densities and size frequency distributions of *T. gratilla* derived from field monitoring activities in 2004 -2007 in selected sites in NW Luzon (Fig. 1) were analyzed to gain more insights on the ecological impacts of restocking and grow-out culture of sea urchins.

The total density of sea urchins (individuals 100 m^{-2}) and the density of recruits (<40 mm TD, individuals 100 m^{-2}) at four sites in Bolinao, Pangasinan (Lucero, Silaki Is., Victory and Balingasay, see map inset in Fig. 2) in

2004 to 2007 were compared. Three belt-transects (100 m x 2 m) covering an area of 600 m^{-2}, were surveyed. Sea urchins found within the belt transects were counted and test diameter (TD) was measured to the nearest millimeter using a Vernier caliper. To determine broad scale patterns in recruitment, 6 other locations were surveyed along NW Luzon in January to February 2006 coinciding with the incidence of very high densities of recruits in Bolinao. The four localities surveyed north of Bolinao were Santiago and Nalvo in Ilocos Sur, Paraoir and Poro Point in La Union (Fig. 1). There was on-going grow-out culture of sea urchins in these sites. Whenever possible, additional transects were laid at different distances (10 m apart up to 50 m) from the area of the grow-out cages and another transect in an area with no grow-out cages. South of Bolinao, surveys were conducted at the Hundred Island National Park in Alaminos, Pangasinan (inside Lingayen Gulf) and at three sites in Masinloc, Zambales (Fig. 1).

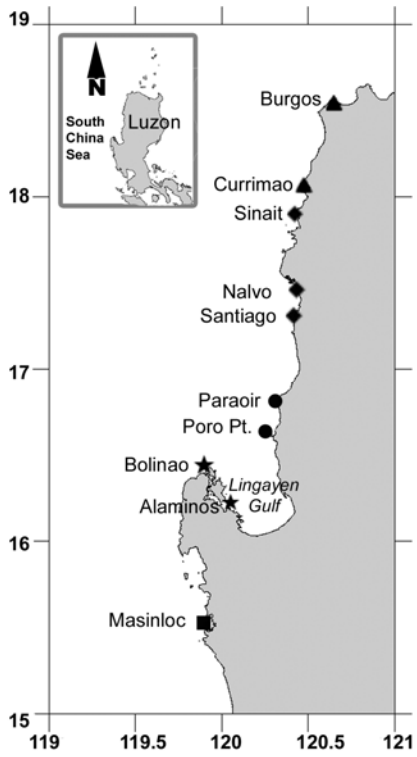

Figure 1. *T. gratilla* monitoring sites in Northwestern Luzon, Philippines. Site legends indicate localities in five provinces: triangle – Ilocos Norte, diamond – Ilocos Sur, circle – La Union, star – Pangasinan, square – Zambales.

Additional surveys were conducted in Poro Pt. in 2006 and 2007 to validate the reported increase of recruits in the area after the initiation of sea urchin grow-out culture. These were compared with densities from a previous survey in December 2003. Monitoring surveys were conducted in three other localities in the Ilocos region (i.e. Sinait, Currimao, Burgos, Fig. 1) from November 2006 to August 2007 in 3 permanently marked sites (2 m x 20 to 50 m), to compare densities and size structure of *T. gratilla* populations.

Results

Variation in Recruitment Strength Among Sites

In Bolinao, >10 individuals 100 m^{-2} was observed for the first time in 2004 since the collapse of the fishery in 1992. The highest density recorded was 460 individuals 100 m^{-2} (of which 80 % were recruits) in Lucero in January 2006 (Juinio-Meñez et al., 2008). Overall, total densities and density of recruits in the three other sites were significantly lower ($p<0.05$) than those in Lucero for the same sampling periods in 2004 to 2007. Notably, there was a positive relationship between the average density of recruits and adults at the four sites during surveys in 2004-2007 (Fig. 2).

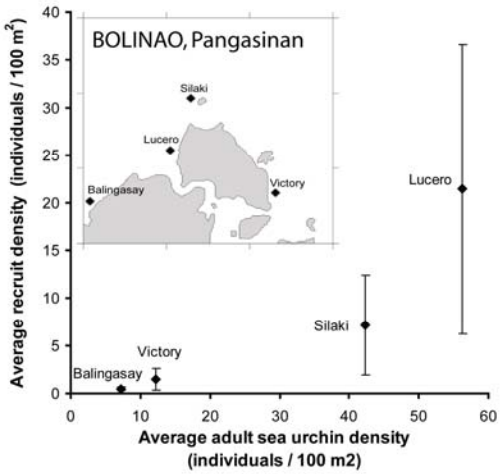

Figure 2. Average density of *T. gratilla* recruits plotted against the adult average densities in Bolinao sites.

A survey in other locations along NW Luzon in early February 2006 showed the presence of recruits in all sites except at the Hundred Island National Park in Alaminos. The modal size class of all sea urchin populations ranged from 3-5 cm TD (Fig. 3). This suggests that the recruits of the year were primarily from larvae, which settled during the previous 3-5 months (September–November 2005), coinciding with the peak of the SW monsoon.

Total density and density of recruits in the sites surveyed in Ilocos Sur, La Union and Zambales during the same period ranged from 10-60 individuals 100 m^{-2}, about an order of magnitude lower than that in Lucero, Bolinao. The harvesting of juveniles for grow-out culture in these areas confounded the estimated densities in Ilocos and La Union. Nonetheless, the density of sea

urchins decreased with distance from the grow-out cages in Paraoir and Santiago (data not shown). This observation was consistent with anecdotal accounts of fishers engaged in grow-out culture. In Poro Point and Nalvo, growers also observed higher numbers of juvenile sea urchins near the cages. However no pattern was evident from the field survey results.

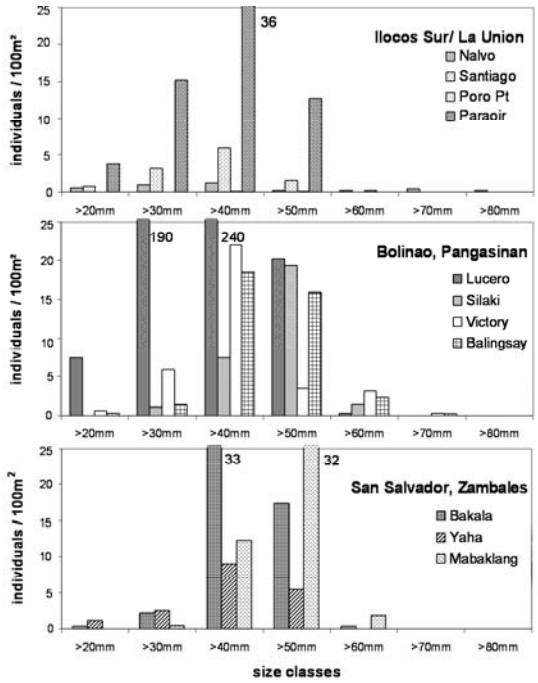

Figure 3. Size frequency distribution of sea urchins in various sites in Northwestern Luzon on January - February 2006.

Monitoring surveys in other sites in the Ilocos region showed significant differences in mean density of *T. gratilla* among the three sites surveyed. Mean densities in Sinait were significantly higher compared to Currimao and Burgos (Table 1). During the November 2006 and February 2007 surveys, early juveniles (10-30 mm TD) comprised about 67% of the total sea urchins sampled in Sinait. Overall, juveniles (< 40 mm TD) were more abundant in Sinait during most sampling months while in Currimao and Burgos, late adults (<70 - >90 mm TD) urchins were more abundant.

Recruitment before and after initiation of grow-out culture in sea cages

Densities of *T. gratilla* increased in Poro Pt., after the initiation of grow-out culture in December 2005 (Fig. 4). Starting September 2006, juveniles comprised 79-83% of the total counts, validating the report of locals on the high incidence of juveniles. Prior to grow-out culture, density of sea urchins in the area was very low. In fact, juveniles for the sea urchin grow-out cages were sourced from a neighboring town (Paraoir). Higher densities of juveniles were found in the monitoring sites inside the embayment. However, there was no positive relationship between abundance of juveniles relative to distance from the grow-out cages up to 50 m.

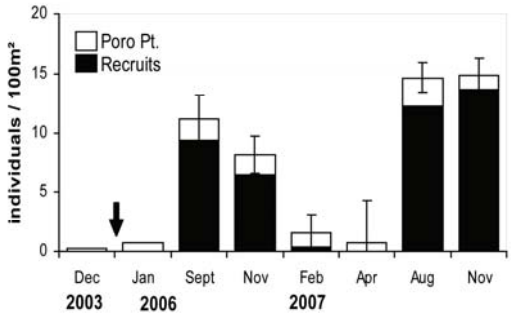

Figure 4. Mean sea urchin density in grow-out site in Poro Pt., La Union. Arrow indicates the start of grow-out culture.

Discussion

The positive correlation in the density of recruits and adults in the four sites in Bolinao, the high incidence of recruits in Lucero and Sinait relative to other sites without sea urchin grow-out culture, and the significant increase in the density of juveniles after the initiation of grow-out culture in Poro Pt. strongly indicate that the aggregation of adults in the grow-out cages enhanced benthic recruitment. In addition, the higher density of sea urchins near the grow-out cages in Paraoir and Santiago during the February 2006 survey validated the anecdotal accounts of fishers engaged in grow-out culture.

Similarly, recruitment strength of *Diadema antillarum* in Barbados was positively correlated with adult densities. Juvenile mortality was low in adult settlement sites and juveniles aggregated in reefs with adult populations. These suggested that regionally dispersed larvae may prefer areas of high adult density (Hunte and Younglao 1988). Compounds from conspecific sea urchins can act as settlement cues for larvae (reviewed in Hugget et al. 2006; Swanson et al. 2006) as described in several benthic marine invertebrates (reviewed in Rodriguez et al. 1993).

Table 1. Overall mean density of *T. gratilla* (individuals 100 m^{-2}) in the three study sites in Ilocos over a ten-month sampling period. Means with the same letters are not significantly different from each other (ANOVA p>0.05, Tukeys HSD test). Standard error values are in the parentheses.

Dworjanyn and Pirozzi (2008) found that *T. gratilla* larvae settled at a higher rate in the presence of live juveniles and their faeces. Settlement near conspecifics provides the advantage of settling in a habitat that can more likely support post-larval growth (reviewed in Pawlik, 1992) and for some species, may provide protection from predation as observed for *Strongylocentritus franciscanus* wherein juveniles were protected by adult spine canopies (e.g. Tegner and Dayton 1977; Tegner and Dayton 1981).

In general, gregarious behavior and high densities in echinoids have been reported to increase fertilization success (Pennington 1985; Levitan 1991; Levitan et al. 1992; Levitan 2004). Likewise, a population genetic study on the red sea urchin *Strongylocentrotus franciscanus* suggests that high population densities are required for successful fertilization (Burton 2003). Clearly, behavior and critical thresholds in density are important considerations in the establishment of marine protected areas (e.g. Dayton et al. 2000). The very high recruitment success of *T. gratilla* in Lucero compared to other sites in Bolinao appears to be due to the synergy of favorable fin scale biophysical factors and local management interventions that enhanced build-up of the spawning population. In particular, the maintenance of the broodstock for the hatchery and juvenile grow-out cages, the strict enforcement of the marine sanctuary and prohibition of harvesting of small-sized sea urchins in the area reestablished adult populations (Juinio-Meñez et al. 2008).

Since the sea urchins in the grow-out cages are not harvested until they are sexually mature (>6 mm TD) and aggregations in the cages may enhance fertilization success, they maybe local sources of larval supply. The marked increase of recruits in Poro Pt. after the initiation of grow-out culture may be attributed to the high entrainment potential in this site. Based on coastal rugosity and wake formation studies, both Poro Pt. and Bolinao were identified to have high entrainment potential that could concentrate larvae locally and facilitate self-recruitment (Magno 2005). Swearer et al. (2002) proposed that positive stock-recruitment relationships over small spatial scales (e.g. 10s kms), which have been documented for species with a wide range of pelagic larval development periods, are indicative of self-recruitment. Moreover, stronger evidence for self-recruitment based on positive stock-recruitment relationships may be derived from the quantification of local recruitment following localized stock enhancement, as evident in the results for Bolinao and Poro Pt. in this study.

On a broader scale, the modal size range for the different populations monitored during January and February 2006 indicate similar temporal patterns in reproduction of populations in the region. The recruits (3-5 mm TD) are likely from spawning events in May-August based on juvenile growth rates and larval duration under culture conditions (Juinio-Meñez and Hapitan 1998). Larval dispersal modeling studies in NW Luzon suggest that *T. gratilla* populations are highly connected by larval transport due to the reversing monsoons (Juinio-Meñez and Villanoy 1995). Population genetic studies using allozyme also provide some evidence of extensive gene flow between *T. gratilla* populations (Malay et al. 2002). Thus, while self-recruitment is highly likely in some sites like Lucero and Poro Point, there is also high larval exchange among populations in NW Luzon.

Given the high potential for larval exchange among localities and the reproductive biology of this species, establishment of a network of marine protected areas and grow-out culture are strategic in conserving larval sinks and sources for *T. gratilla* in the region. Further investigations on fine-scale and meso-scale hydrographic conditions together with genetic studies using DNA markers may further elucidate factors that influence the recruitment dynamics of populations and provide inputs to ensure the sustainability of the fisheries in NW Luzon.

4) Virgin Islands National Park, National Park Service, St. John, USVI

Abstract
NOAA's Biogeography Branch, National Park Service (NPS), US Geological Survey, and the University of the Virgin Islands (UVI) are using acoustic telemetry to quantify spatial patterns and habitat affinities of reef fishes. The objective of the study is to define the movements of reef fishes among habitats within and between the Virgin Islands Coral Reef National Monument (VICRNM), the Virgin Islands National Park (VIIS), and Territorial waters. In order to better understand species' habitat utilization patterns among management regimes, we deployed an array of hydroacoustic receivers and acoustically tagged reef fishes. A total of 150 fishes, representing 18 species and 10 families were acoustically tagged along the south shore of St. John. Thirty six receivers were deployed in shallow nearshore bays and across the shelf to depths of approximately 30m. Example results include the movement of lane snappers and blue striped grunts that demonstrated diel movement from reef habitats during daytime hours to offshore seagrass beds at night. The array comprised of both nearshore and cross shelf location of receivers provides information on fine to broad scale fish movement patterns across habitats and among management units to examine the strength of ecological connectivity between management areas and habitats.

Key words: Acoustic Tracking, Coral Reef, Fish, Habitat Utilization, Telemetry

Introduction

Study Area and Background

Coral reefs in the US Virgin Islands and in Virgin Island National Parks have declined in recent decades. The establishment of the Virgin Islands Coral Reef National Monument (VICRNM) in 2001 provides approximately 5,143 hectares of additional NPS marine managed area off the island of St. John, USVI. To assess the long-term effectiveness of management regulations and VIIS and VICRNM as marine protected areas (MPAs) it is necessary to conduct investigations that can provide data on the movement of reef fishes within areas across and outside NPS boundaries. NOAA digital benthic habitat maps coupled with movement patterns of fishes provide a spatial framework to address questions concerning linkages among adjacent habitats and how the mosaic of habitats connect in the seascape that structure reef fish distribution patterns.

Material and Methods

Island Scale

To determine the movements of reef fishes along the entire south shore of St. John and portions of its eastern bays within and outside VICRNM and VIIS, 36 receivers were deployed (Fig. 1).

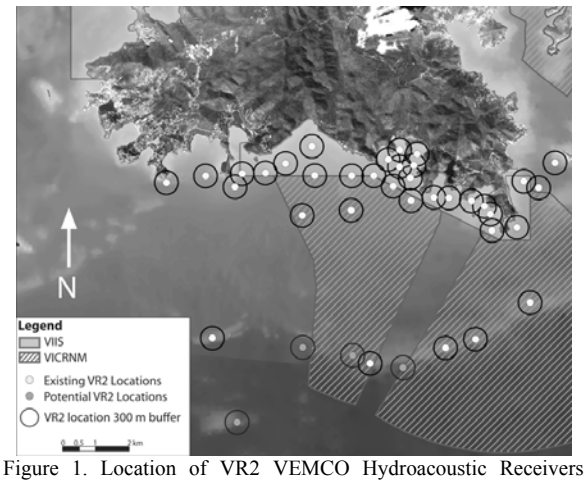

Figure 1. Location of VR2 VEMCO Hydroacoustic Receivers around St. John, USVI.

Each of the acoustic receivers has a nominal detection range of 300m. Based on our knowledge of the distribution of habitats and reef fish ecology, we

deployed receivers in shallow nearshore bays and across the shelf to depths of approximately 30m. Receivers were located within reefs and adjacent to reefs in seagrass, algal beds, or sand habitats and within and outside of VIIS and VICRNM. This array provides data to define "island scale" patterns of reef fish movements.

Fine Scale

To define fine scale movement of reef fishes and their habitat affinities, of the 36 receivers found within the entire array, 9 of these receivers were concentrated in the Lameshur Bay complex. The receivers were deployed to ensure "overlap" among detections of acoustically tagged fishes and to ensure all habitats within the bay were covered by the fine scale array (Fig. 2).

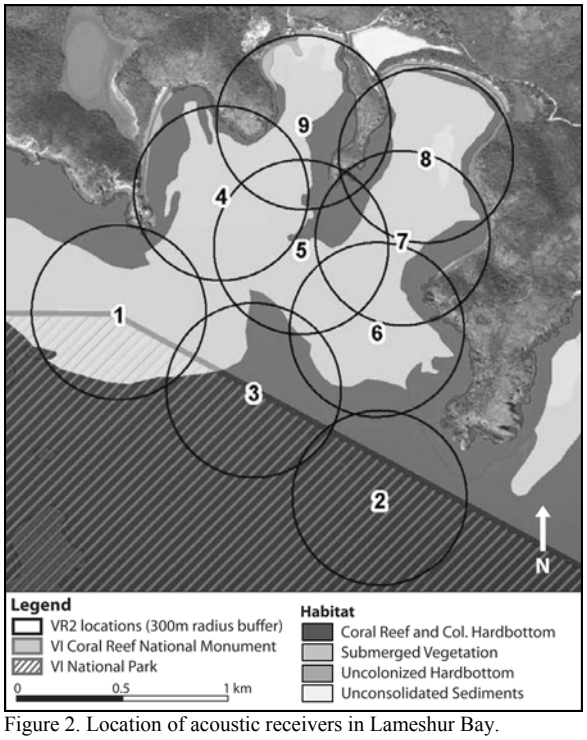

Figure 2. Location of acoustic receivers in Lameshur Bay.

Acoustic Tagging

We surgically implanted VEMCO V9-2L-R64K transmitters into the stomach cavities of captured fishes (Fig. 3). A 1cm incision was made 1cm off-center from the ventral midline behind the pelvic fins and a small acoustic transmitter (22mm) was placed within the body cavity. The incision was closed with two surgical sutures and the fish were observed to ensure adequate recovery. After holding fish for 24 hours in post surgery recovery tanks, they were released at a location in close proximity to their original capture location.

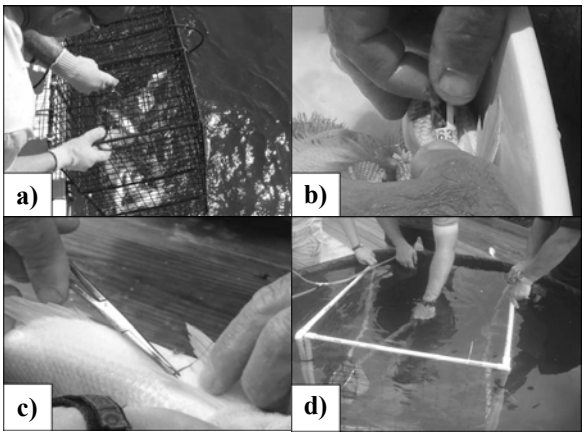

Figure 3. a) Fish traps used to capture fish; b) surgical implanting of acoustic transmitters; c) closing incision with surgical suture; and d) a crowder used to minimize handling and stress in the holding/ recovery tank.

Results

Lameshur Bay-wide Habitat Utilization

The greatest number of total detections were recorded at Station 5 (55%), followed by Station 3 (20%), and Station 6 (16%), respectively (Fig. 4). This is despite the fact that 51% of all of the releases during this period of the study (July 2006 to April 2007) occurred at Station 6, with 27% released at Station 5 and 22% at Station 4. In addition, the receiver at Station 5 stopped collecting data after December 15, 2006 due to memory limitations. The dense seagrass bed adjacent to Yawzi Point (Station 5) may have resulted in shorter migration distances to nighttime foraging areas that were still within the detection range of Station 5 (Fig. 5).

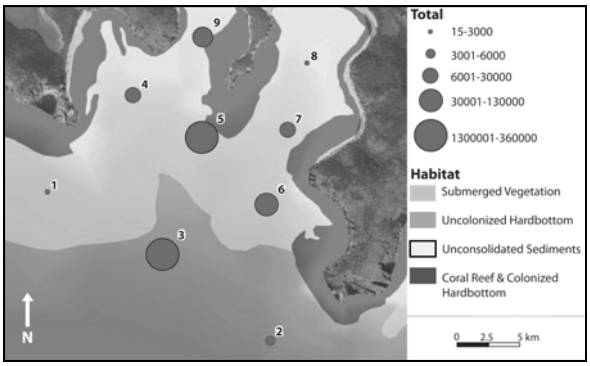

Figure 4. Total number of detections by receivers from July 2006 to April 2007.

*Individual Fish Movement – Lane snapper (*Lutjanus synagris*)*

Figure 6 is a plot of receiver detections for an individual lane snapper (29cm TL) undergoing sun-synchronous migrations into and out of Lameshur Bay between July 12, 2006 and April 5, 2007 (268 days; night= 0:00-4:00 and 20:00-24:00, crepuscular= 4:00-8:00 and 6:00-20:00, daytime=8:00-16:00). The

data indicate daytime site fidelity with the eastern side of Lameshur Bay and a regular departure from the bay at sunset and a return to the bay at sunrise.

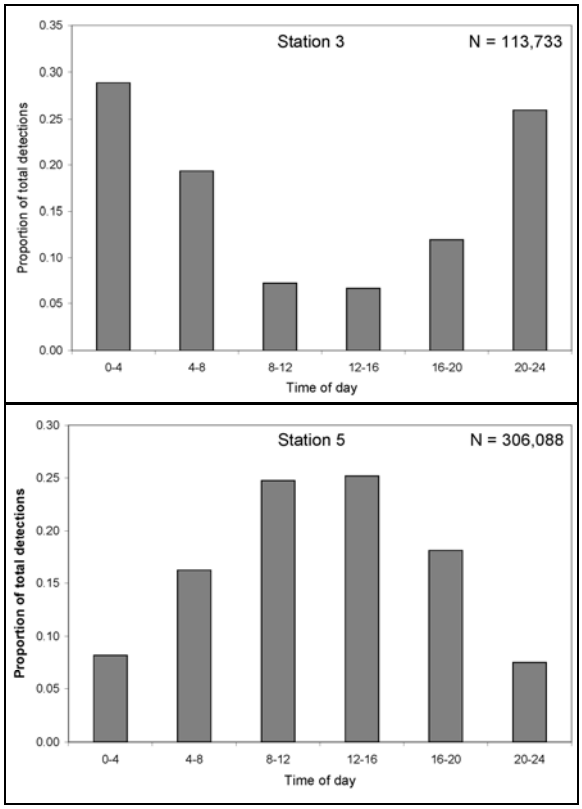

Figure 5. Proportion of total detections by time of day for: a) Station 3 and b) Station 5.

This movement pattern is further highlighted in Figure 7 that shows at approximately sunset this fish was detected at Station 2 and was likely leaving the bay since it was not detected on any other receiver at night. It appears the fish migrated offshore into deeper water to presumably to forage and returned back to Lameshur Bay at sunrise.

Discussion

The joint NOAA, NPS, USGS, and UVI acoustic tracking of reef fishes found around St John, USVI is providing a wealth of information to define reef fish movements and habitat utilization patterns. These data have been and will continue to be used to define the ecological connections between the VIIS, VICRNM, and USVI Territorial waters. This work directly supports NPS and Territorial management of living marine resources by evaluating the efficacy of marine protected areas, defining species habitat affinities and determining the temporal patterns of reef fishes at island-wide and fine scale spatial extents.

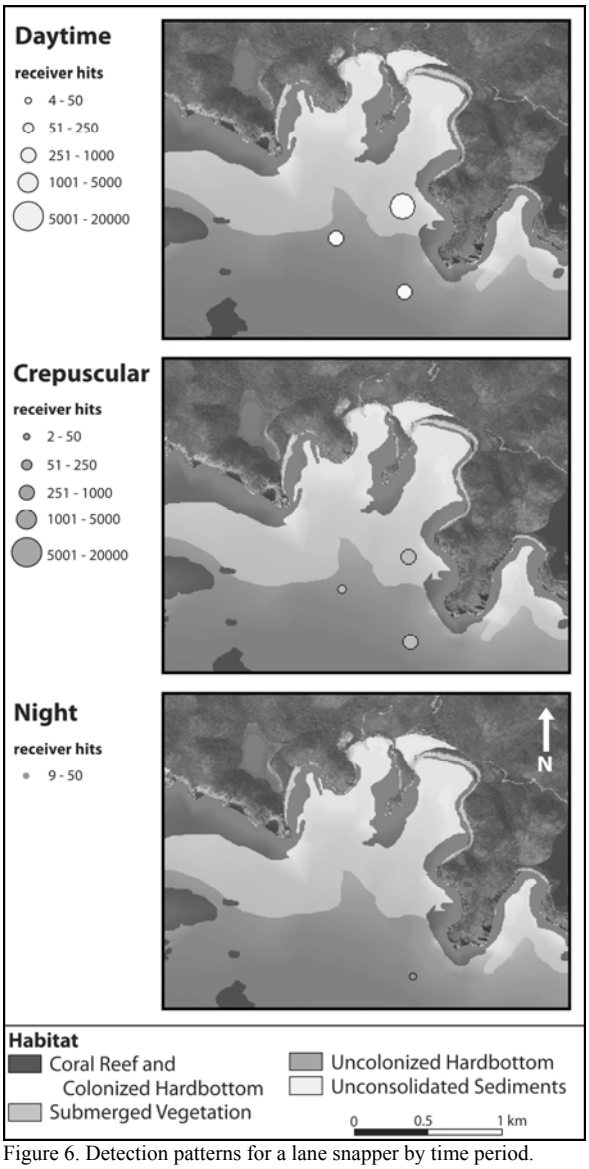

Figure 6. Detection patterns for a lane snapper by time period.

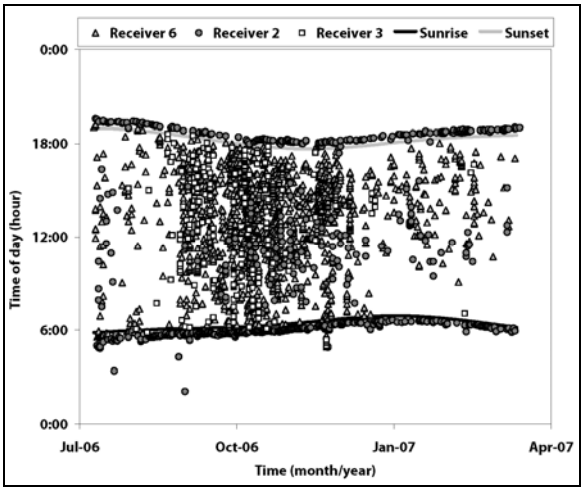

Figure 7. Data for lane snapper indicating sun-synchronous nocturnal migrations and high daytime site fidelity.

The next steps in the work are to continue to analyze the acoustic returns of individual fishes detected across the receiver array and to deploy 4 additional receivers to better elucidate the connectivity between the relatively deep mid-shelf reef area found offshore of southern St. John and within the VICRNM to VIIS and nearshore territorial waters. Plans are to continue the study to at least December of 2009 and then determine if and when to move the receiver array to additional locations within the USVI.

Acknowledgements

This study was made possible by the dedicated efforts of the CCMA and NPS staff and funded by CCMA, NPS, USGS, and NOAA's Coral Reef Conservation Program. We thank the staff at the Virgin Islands Experimental Research Station for their support and use of laboratory facilities.

Banggai cardinalfish: towards a sustainable ornamental fishery

S. Ndobe[1], A. Moore[2]
1) Sekolah Tinggi Perikanan dan Kelautan, Jalan Soekarno-Hatta, Kotak Pos 1016, Palu 94118, Central Sulawesi, Indonesia, email: samndobe@yahoo.com
2) Yayasan Palu Hijau, Jalan Setia Budi Lorong Siswa No12, Palu 94111, Central Sulawesi, Indonesia, email: abigail2105@yahoo.com

Abstract. Central Sulawesi Province has over 4,500km of coastline and over 700 islands including the Banggai Archipelago. Established as Banggai Kepulauan District in 1999 and covering almost all the native distribution of the Banggai cardinalfish, *Pterapogon kauderni,* though introduced populations have become established elsewhere. A paternal mouth brooder with direct development traded in large numbers as an ornamental fish, *P. kauderni* was recently proposed for listing in CITES Appendix II and has since been listed as Endangered on the IUCN (International Union for the Conservation of Nature) Red List. Local activities to develop sustainable management of *P. kauderni*, underway since 2005, aim to address concerns regarding the Banggai cardinalfish fishery and trade as well as habitat conservation. The CITES proposal in 2007 brought the Banggai cardinalfish into the limelight at national and international levels, and a multi-stakeholder multi-year national Banggai Cardinalfish Action Plan has been developed. Developments since 2004 are outlined including initiatives under the Sea Partnership Program; local research and some recent results; and early progress in implementing the Action Plan, including the establishment of the BCF Centre, District and village marine protected areas and a Banggai cardinalfish trade monitoring system.

Key words: Banggai cardinalfish, Sulawesi, ornamental fishery.

Introduction

The Banggai cardinalfish *Pterapogon kauderni* (Koumans, 1933) is an endemic, reef-associated fish with a distribution limited to the Banggai Archipelago in Central Sulawesi, Indonesia and a few nearby islands (Fig. 1). Some introduced populations have become established along the trade routes, including sites in North Sulawesi (Erdmann & Vagelli, 2001), Palu Bay (Moore & Ndobe, 2007a) and North Bali (Lilley, pers.com).

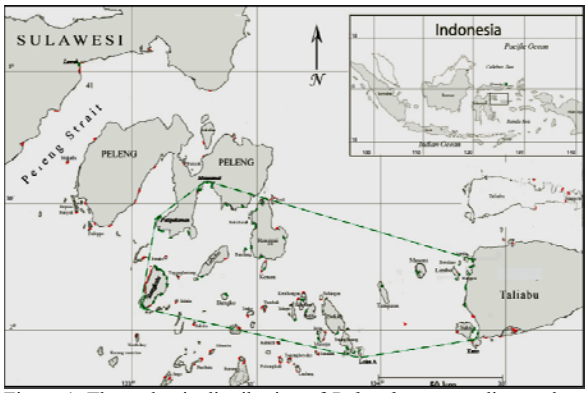

Figure 1: The endemic distribution of *P. kauderni* according to the CITES proposal (Vagelli, 2005 *in* Anonymous, 2007a).

The male incubates the eggs (around 20 days) and larvae (around 9 days) in his mouth, and fasts for this period On release juveniles immediately seek shelter and food in available nearby habitat, with no pelagic dispersal phase, cannibalism by the (male) parent and other adult fish is common (Vagelli, 1999).

Locally known as *bebese tayung*, which in Bajo (sea gypsy) language means little fish in the sea urchins, since the early 1990's the Banggai cardinalfish has been internationally traded as an ornamental fish (Ndobe & Moore, 2007).

Discovered by Kaudern and classified by Koumans in 1933, *P. kauderni* was "forgotten" by the scientific community until it was "rediscovered" in 1994 (Allen & McKenna 2001). In the following 10 years there was much international interest and a considerable amount of research into the biology, ecology and exploitation of the species by visiting scientists who generally considered the trade to be unsustainable (Allen and McKenna 2001; Lunn and Moreau 2004; Kolm and Berglund 2003; Vagelli and Erdmann 2002).

Key data and information were available at international level since 2001 or even earlier but in general were not communicated to local or national

stakeholders and therefore had no impact on management (Ndobe & Moore, 2007).

Material and Methods

The paper presents a synopsis based on literature and on personal experience during the process of local awareness building regarding the Banggai cardinalfish followed by early steps in developing management activities over the period from October 2004 to the 11th ICRS in July 2008.

2004-2005: Initial Awareness Building

A case study in the Banggai Islands was undertaken by the NGO Yayasan Palu Hijau as one of several short case studies in three countries commissioned by NACA (Network of Aquaculture Centres in Asia), coordinated in Indonesia by the STREAM (Support to Regional Aquatic Resources) Hub at the Directorate General for Aquaculture, under the ECPREP (European Community Poverty Reduction Effectiveness Program) project entitled "The International Seafood Trade: Supporting Sustainable Livelihoods Among Poor Aquatic Resource Users in Asia" (EC-PREP, 2005). The main overall project aim was to identify mechanisms for reducing poverty associated with the ornamental fish trade.

The Banggai cardinalfish was found to be the main ornamental species caught by local rather than "outside" fishers and heavily (over) exploited. The fishery was poorly managed from capture through post-harvest handling and husbandry to packing and transport. The market chain was long and complex and trading patterns were often unfair and inefficient. Direct and indirect threats to *P. kauderni* populations and habitat including threats to and from other fisheries were identified. However, observations and data also indicated the possibility of a sustainable fishery. Indeed the highest population density was recorded at a site where collection had been carried out for some years on a periodic basis, with rotation between sites.

The results were presented to stakeholders at District (local), Provincial and National level. The local stakeholders recognised that action was needed. An outline program was agreed to and proposals drawn up.

2006: The First Steps

Implementation of the plans developed in 2005 began in 2006 with support from the Sea Partnership (Mitra Bahari) Program of the Department for Marine Affaires and Fisheries through the Central Sulawesi Regional Centre Sea Partnership Consortium (KMB). The KMB partners include local Universities/Higher Education Institutes and NGOs, as well as local government agencies.

Activities undertaken included a survey of *P. kauderni* populations, habitat and exploitation in Banggai Island, which along with the data from 2004/2005 formed the basis for further local awareness building, in particular through a Marine Protected Area (MPA) Management training and workshop. As a result, two villages (Bone Baru and Tinakin Laut) decided to establish community MPAs and a local organisation for MPA development was founded.

Research into *in-situ* breeding of the Banggai cardinalfish was carried out, based on a model developed by Dr Kolm, involving undergraduate students and the introduced population in Palu Bay (Ndobe & Moore, 2007; Moore & Ndobe, 2007a). The results raised a number of questions and challenged some conclusions in the scientific literature on *P. kauderni*. Further research was planned and is still ongoing.

The key results of these and other activities were included in two books published in Indonesian as part of the KMB 2006 program. One book was on the biology, ecology and conservation of the Banggai cardinalfish and the other on the fishery and trade.

2007: CITES CoP 14 and local impacts

In early 2007 the Department of Marine Affaires and Fisheries contacted the Central Sulawesi Provincial Fisheries Service to request information about *P. kauderni* in connection with the proposal submitted by the United States of America to list the species on CITES Appendix II at the 14th Conference of the Parties (CoP) in June 2007. News of this proposal came as a great surprise to stakeholders in the endemic distribution area who had no idea that such a proposal was being prepared much less already submitted (Moore & Ndobe, 2007b).

The FAO expert panel (FAO, 2007) did not support the listing on scientific grounds. It is now history that the proposal was withdrawn and that Indonesia made a strong public commitment to Banggai cardinalfish conservation (Anonymous, 2007b).

Local Activities pre and post CITES COP 14

In addition to providing data and information to many parties including the Indonesian authorities and delegates, the FAO expert panel, the IUCN working group and others, local activities included research funded by the Higher Education Department (DIKTI) junior lecturer research programme into the phenomena of ontogenetic shift in micro-habitat first put forward by Vagelli (2004).

This research, some of which has since been presented in local and national meetings (e.g. in Ndobe & Moore, 2007), was carried out in the native habitat (three habitat types: coral reefs, seagrass beds and reef flats) around Tinakin Laut, Banggai Island and at the introduced population site in Palu Bay (homogenous habitat). The results revealed no significant difference between habitat types, but

indicated a strong preference of new recruits and small juveniles for sea anemone micro-habitat, even when *Diadema* sea urchins were abundant (Fig.2).

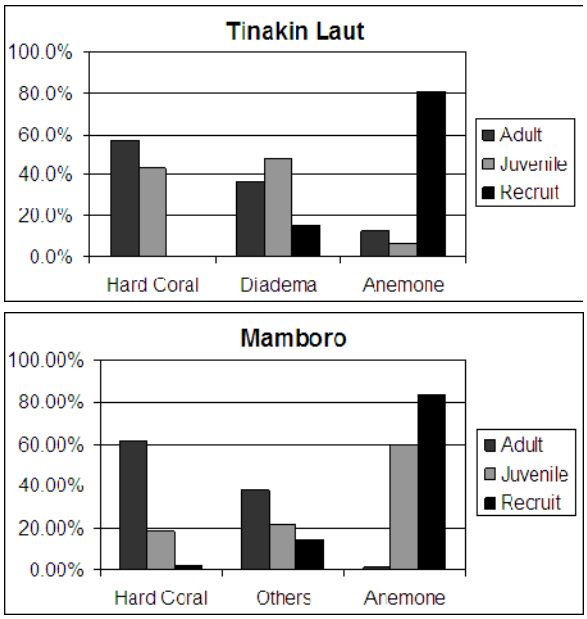

Figure 2: Size/age class distribution by micro-habitat at Tinakin Laut (Banggai Island, top) and Mamboro (Palu Bay, centre))

In addition, the highest numbers of uniform size (apparent sibling) groups of recruits and small juveniles were recorded in anemone micro-habitat. An important management implication is the need to conserve sea anemones, which were overexploited for human consumption.

Hard corals seem important for adults, and (as in 2004 and 2006), some survey locations were under severe attack from a population explosion of the corallivorous starfish *Acanthaster plancii*. The results also raised questions regarding the periodicity of Banggai cardinalfish breeding and indicated that seasonal factors may influence breeding patterns, success or possibly both.

Banggai Cardinalfish Action Plan

After CITES CoP 14, a national level meeting was held in Palu, capital of Central Sulawesi, attended by senior officials from the Department of Marine Affaires and Fisheries, Provincial and District Governments, fishermen, local leaders, local and national NGOs and Academia. A multi-year action plan for sustainable management of the Banggai cardinalfish was drawn up. A synopsis of this plan (translated from the original) is described in Fig 3.

2008: Early achievements and constraints

Initial steps in implementation during 2007 included the establishment of the BCF Centre (Decree No 168/2007 of the Banggai Kepulauan District Head), and a Marine Protected Area (Decree No. 540/2007).

Activities underway and planned for 2008/2009 include:

(i) Support (mainly from the Provincial Fisheries Service in partnership with NGOs and Higher Education Institutes) for the MPAs proposed by the village communities of Bone Baru and Tinakin Laut, in the form of training, physical facilities, etc. It is anticipated that the two community MPAs will become functional during 2009.

(ii) The drafting of a Ministerial Decree regarding the (sustainable) management of the Banggai cardinalfish is in progress, completion anticipated in early 2009

(iii) Development of the BCF Centre, working closely with ornamental fishers and local traders. Despite funding constraints, anticipated activities include socialisation and management planning.

(iv) Ongoing research by local scientists (including the involvement of undergraduate students) into various aspects of Banggai cardinalfish biology, ecology and husbandry, both *in-situ* and *ex-situ,* involving the Banggai Cardinalfish Unit established at the Provincial Fisheries Hatchery Complex at Mamboro in Palu Bay, the Fisheries and Marine Higher Education Institute (STPL-Palu), the Aquaculture Study Programme at Tadulako University and other Sea Partnership members. Results to date have shown that there is still much to learn about this fascinating species including the influence of environmental factors on growth patterns.

(v) Captive breeding research (*ex-situ*) at the Ambon Mariculture Research Station, begun in 2008.

(vi) Monitoring of the trade in *P. kauderni* by the Fisheries Resources Directorate in partnership with the District Fisheries Service, begun in 2008.

(vii) Survey/monitoring of *P. kauderni* populations, planned during 2009/2010.

(vii) Training for fishers in partnership with the Marine Aquarium Council (MAC), possibly in 2009.

(viii) Distribution of a Children's book by Yayasan Palu Hijau with support from PADI Project AWARE, the title means "The little beauty in the sea urchins".

Conclusion: Quo Vadis, BCF?

Since local awareness first began to develop in late 2004 real progress has been made, and the processes associated with the CITES proposal certainly helped raise the profile of *P. kauderni* at local and national levels. However the fact that the Banggai cardinalfish is now listed on the IUCN "Red List" as "Endangered" is a reminder that there is still a long way to go to fulfil the goal of the Banggai Cardinalfish Action Plan, which roughly translates as ensuring the conservation of the species and it's habitat for the benefit of present and future generations. As a key element of the conservation strategy there is a realistic chance that a sustainable ornamental fishery will be developed for this attractive reef-associated fish with an unusual lifecycle whose beauty has nearly been its downfall.

Acknowledgements
The authors wish to express their gratitude to the many organisations and individuals who supported the activities outlined above, including the EC-PREP, NACA, and STREAM Indonesia team, especially Aniza Suspita and Mike Philipps; the Sea Partnership (Mitra Bahari) Program; The Indonesian Education Department (DIKTI) research grants programme; PADI Project AWARE; Reef Check Indonesia; the Marine Aquarium Council; GEF Small Grants Programme; Dr Kolm; the STPL-Palu and YPH teams; the Provincial and District Fisheries and Marine Services; the Banggai Kepulauan BCF fishers, and other local stakeholders; Dr Suseno and many colleagues from the Department for Marine Affaires and Fisheries as well as many other individuals and organisations who are too numerous to mention individually. Special thanks are due to Tonny Wagey, Jill Heyde, Akhdary Supu, Ederyan, Dewi and all who in any way assisted in the production and presentation of this paper.

Differential depth effects upon biomass patterns in an herbivorous coral reef fish assemblage.

M. Nemeth[1]

1) University of Puerto Rico, Department of Marine Sciences, PO Box 908, Lajas, Puerto Rico 00667

Abstract. The abundance of parrotfish and surgeonfish on fore-reef habitat was sampled on 6 reefs along an inshore-offshore gradient in La Parguera, Puerto Rico to provide for within reef (across depths) and among reef (cross-shelf) comparisons. Temporally replicated visual surveys were conducted along permanent belt transects ($100m^2$) at three depth intervals (3, 10, 15 m) to obtain data on fish species density and lengths used to calculate biomass. The herbivorous fish assemblage was dominated by small-bodied parrotfish *Scarus iseri*, *Sparisoma aurofrenatum S. viride* and *Acanthurus coerulus*. Overall the density and biomass of parrotfish and surgeonfish was higher at 3m than at 10 or 15m. However, the differences in biomass across the depth gradient were most notable at inshore reefs where the proportional decrease in biomass by depth was higher compared to the mid-shelf reefs. Depth is a well know driver of herbivorous fish abundance, but along a cross-shelf gradient additional within reef factors interact to structure biomass patterns.
Key words: Reef fish, grazing, depth gradient.

Introduction

Grazing by Parrotfish (*Scaridae*) and Surgeonfish (*Acanthuridae*) is an ecological process that structures coral reef benthic communities (Hughes 1994; Belliveau and Paul 2002). Spatial variation in the abundance of these herbivores can result in differential grazing pressure and may have implications to coral-algal interactions (Lewis and Wainwright 1985; Mumby et al. 2006). At a basic research level the patterns in fish distribution on a reef may indicate underlying processes that influence how fish use available habitats. At an applicable level understanding the processes that structure the abundance of parrotfish and surgeonfish will aid in managing for this important ecological function. Understanding the spatial patterns of parrotfish and surgeonfish on fore-reef habitats along an inshore-offshore gradient will help determine factors that structure this fish assemblage (Williams and Polunin 2001; Paddack et al. 2006; Fox and Bellwood 2007).

This study investigates spatial patterns of parrotfish and surgeonfish biomass on fore-reef habitats across the seascape asking: What area the relative abundances of the species from these two families on the fore-reefs of Southwest Puerto Rico? How are parrotfish and surgeonfish distributed spatially across the fore-reef zones in terms of density and biomass? Are the patterns in abundance consistent between the inner-shelf and mid-shelf reefs?

Material and Methods

Fish abundances were sampled on 6 reefs on inner-shelf and mid-shelf reefs to allow within reef (across depths) and among reef (cross-shelf) comparisons (Fig. 1).

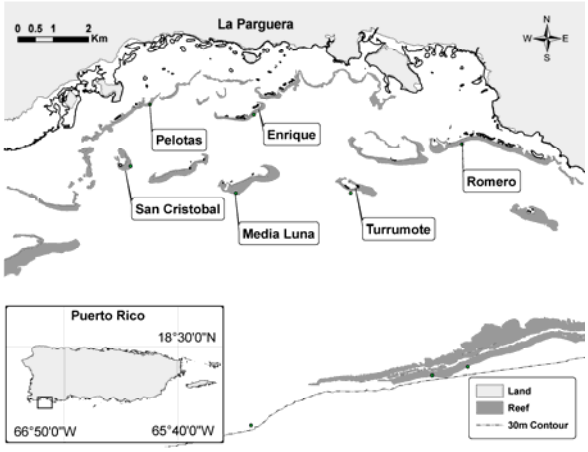

Figure 1: Map of the 6 study reefs (3 inner-shelf: Pelotas, Enrique, Romero; and 3 mid-shelf: San Cristobal, Media Luna, Turrumote).

Visual surveys were conducted along permanent belt transects (25 x 4m). Three depth intervals were selected on the fore-reef slope (3, 10, 15 m), and 3 replicates per depth were sampled 4 times per year. Fish species counts and fork lengths were recorded for each transect. Length data were used to calculate mean sizes and biomass was derived from published length-weight relationships (Ref). Data were analyzed for patterns across depths and between inner and mid-shelf strata by species and at the family level. Kruskal-Wallis (KW) non-parametric ANOVA was used to test for significant differences.

Results

The assemblage of roving herbivorous fish on the fore-reef was dominated numerically by small bodied species. The parrotfish were principally represented by 3 species: *Sparisoma aurofrenatum*, *S. viride* and *Scarus iseri* with the highest densities. Large bodied Scaridae such as *S. guacamia* and *S. vetula* were present but at very low densities and these were generally sighted on the same study reefs. Three species of surgeonfish are present and *Acanthurus coerulus* was numerically dominant.

Across all reefs the abundances of both groups were distinctly structured in relation to depth in the fore-reef habitat. Both families exhibited the highest densities and biomass in the shallowest depth interval (3 m) which sharply decreased at the 10 and 15m intervals (Fig. 2, 3). Densities across depth intervals were significantly different for parrotfish (KW, p=0.036) as well as for surgeonfish (KW, p=0.000). Biomass for parrotfish was 2.3 times higher at the 5 m depth interval than the 15 m interval, and for surgeonfish it was 4 times higher.

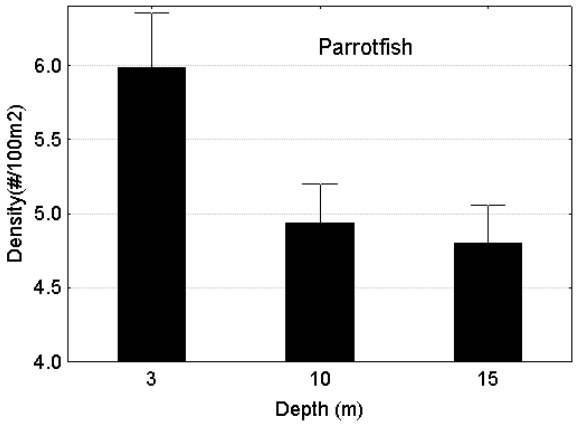

Figure 2: The overall mean density (± SE) of all parrotfish at the 3 depth intervals for the 6 study reefs.

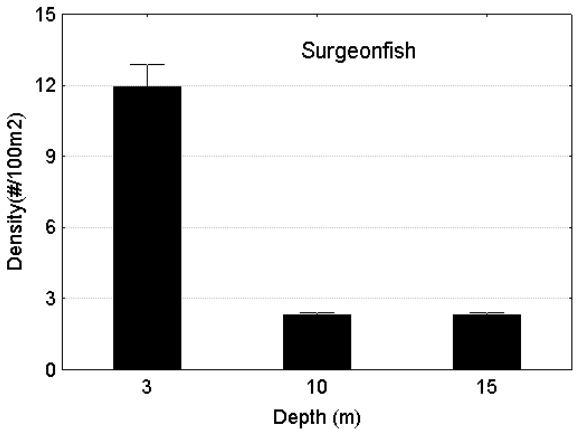

Figure 3: The overall mean density (± SE) of all surgeonfish at the 3 depth intervals for the 6 study reefs.

Comparing the biomass by depth of both families between inner-shelf and mid-shelf reefs revealed that the general trend of decreasing abundances with depth varies between the two strata. The depth-related decrease in abundance is more pronounced at inner-shelf reefs. Biomass for parrotfish on inner-shelf reefs at 3 m was 3.2 times greater than at 15 m; on mid-shelf reefs the proportional difference was 1.8 times greater (Fig. 4). However, comparing the mean biomass of parrotfish between inner and mid-shelf strata for the 3 depth intervals revealed that only the 10m depth interval was significantly different (KW, p=0.003).

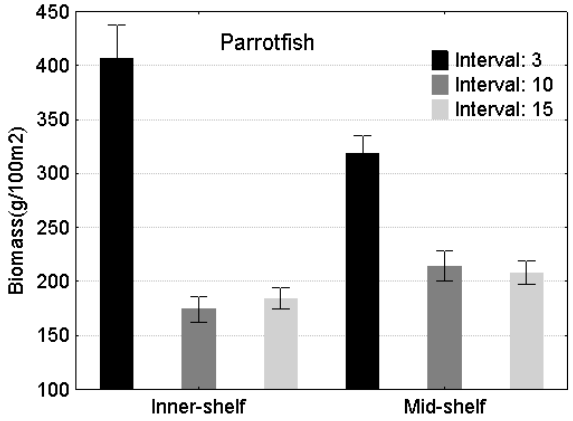

Figure 4: The mean biomass of parrotfish at the 3 depth intervals for inner and mid-shelf reefs, with 95% confidence intervals.

For surgeonfish, biomass on inner-shelf reefs at 3 m was 10.9 times greater than at 15 m; on mid-shelf reefs the proportional difference was 2.8 times greater (Fig. 5). Comparing the mean biomass of surgeonfish between inner and mid-shelf strata for the 3 depth intervals revealed that only the 15m depth intervals were significantly different (KW, p=0.000).

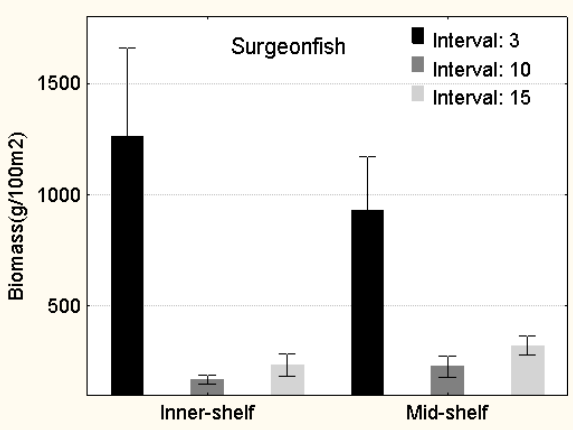

Figure 5: The mean biomass of surgeonfish at the 3 depth intervals for inner and mid-shelf reefs, with 95% confidence intervals.

Discussion

Herbivory is an ecological process that structures coral reef benthic communities and variations in the spatial distribution of herbivores may reflect differential grazing pressure (Mumby et al. 2006). Depth appears to be a major factor that structures the way that parrotfish and surgeonfish utilize fore-reef habitats as has been found in other studies on coral reefs world-wide (Lewis and Wainwright 1985; Hoey and Bellwood 2007).

In this study both the parrotfish and surgeonfish biomass decreased with depth and this was proportionally greater at inner shelf reefs. This effect can vary with reef location, possibly due to factors which are also related to distance from shore, such as water quality (Clifton 1995). Deeper fore-reef habitats seem to be less favorable to grazers which was shown by lower densities and biomass at the deeper depth intervals. This pattern was more pronounced at inshore reefs. These results are in agreement with other studies that have found a peak in herbivorous fish densities in shallow fore-reef zones (Russ 2003; Fox and Bellwood 2007). Maximum abundance at the shallow fore-reef is a result common to most studies on parrotfish and surgeonfish. This may be due to preferential food resources being available from higher productivity of algae at shallower depths (Russ 2003). However, this study documents that this pattern can vary among reefs across an inshore to offshore gradient. The fact that the use of fore-reefs by the dominant species of herbivores is site specific has implications for management strategies that aim to promote fish grazing.

Photo-ID on reef fish – avoiding tagging-induced biases

M. Perrig, B.P.L. Goh

Natural Science and Science Education, National Institute of Education, Nanyang Technological University, 1 Nanyang Walk, Singapore 637616

Abstract. Mark-recapture experiments are essential to estimate population parameters. However, physical tagging is often biased, potentially affecting mortality rates, performance, and behavior. Photo-ID is an unbiased alternative commonly used on marine mammals, but has barely been used on teleost fishes. This study examined the individuality and stability of coloration patterns of two rabbitfish species (*Siganus javus* and *Siganus guttatus*) to determine if photo-ID could be extended to teleost fish. Examination of 189 *S. javus* and 34 *S. guttatus* revealed no duplicated coloration pattern within both species. The coloration patterns of six sub-adult *S. javus* and four adult *S. guttatus* remained easily recognizable over two and eight months, respectively. The results of this study suggest that the coloration patterns of *S. javus* and *S. guttatus* are a reliable means to recognize individuals over time, thus allowing unbiased mark-recapture studies on two coral reef fish species.

Key words: photo-ID, *Siganus javus*, *Siganus guttatus*, coloration pattern

Introduction

Assessing the status of populations and managing them as resources heavily rely on the knowledge of population size and parameters influencing it, namely the BIDE parameters (birth, immigration, death, and emigration; Williams et al. 2002). Many of these parameters can be determined via mark-recapture experiments (Amstrup et al. 2005). However, physically marking animals with tags may have negative impacts on the parameter to be estimated, affecting the reliability of the results (Thorsteinsson 2002). For example, stress due to capture and handling, infection risks, and changed performance may increase post-tagging mortality and therefore bias estimated survival rates (Thorsteinsson 2002).

Mark-recapture experiments using photographic identification (photo-ID) forego tagging induced biases (Amstrup et al. 2005). This technique determines encounter histories by recognizing animals based on naturally occurring morphological features, such as scars, shapes, or coloration patterns (e.g. Speed et al., 2007; van Tienhoven et al., 2007), thus avoiding physical tagging altogether.

This approach has two major underlying assumptions: 1) every individual of a population is sufficiently different from other individuals that they are not misidentified; and 2) features or coloration patterns do not change over the time scale of the study.

It is generally accepted by the research community that no individual is completely identical to its conspecifics. Very important theories are based on such individual variation (e.g. Darwin's evolutionary theory; Campbell, 1995). However, phenotypic differences can be subtle. In practical terms for photo-ID, two coloration patterns could be similar enough to appear identical to an observer, thus leading to misidentifications.

In contrast to generally accepted individuality, the stability of coloration patterns is a major concern using photo-ID. In order to reliably identify an animal, the pattern should not change over the time course of the study. In many fish species, this can potentially pose a problem: Ontogenetic shifts, mood changes as well as growth can induce changes in the coloration pattern (Allen 2002). Alterations due to mood changes are usually very obvious and of little impact to mark-recapture studies.

More important are gradual changes associated with the growth of an animal. Patterns do not necessarily grow in proportion with the body. Gradually expanding patterns by the addition of marks or splitting of dots or lines is also possible. Leopard sharks (*Stegostoma fasciatum*), for example, loose their stripes by dissolving them into spots and rings while growing (Mahon J. L., pers. comm.). Because this is normally a slow and gradual process, it is easily overlooked and therefore may pose a major challenge in photo-ID. Over time, the coloration pattern of an individual might change enough such that it is no longer identified as the same animal.

Photo-ID has been successfully applied on many large and long-lived species, typically marine mammals (e.g. Caswell et al., 1999; Neumann et al. 2002; Langtimm et al., 2004). However, application of photo-ID is by no means restricted to such species.

For example, with their highly ornamented coloration patterns many coral reef fishes are good candidates for photo-ID. Nonetheless, this non-intrusive technique has barely been applied to teleost fish, and data that is unbiased by physical tagging is rare.

This study aimed to extend photo-ID as a reliable technique to two herbivorous fish species on coral reefs: *Siganus javus* and *Siganus guttatus*. The coloration of members from both species was examined over time to establish the temporal extent to which the coloration patterns of these two species could be used as reliable identifiers. Furthermore, patterns were also examined to determine their use for individual identification, and to determine the frequency of coloration duplication. The right and left sides of individuals were also compared to confirm the absence of symmetry.

Materials & Methods

Individuality

A total of 189 *S. javus* and 34 *S. guttatus* were photographed on their right and left sides. Photographs were taken approximately perpendicular to the side of the animal, both from live and dead fish. Live animals were photographed in a small aquarium with little interference. The shape and relative position of dots and lines on the entire body of the fish (excluding fins and head) within each species and side were manually compared with each other. The right and left sides of each individual were also compared with each other.

Comparisons were classified as 'identical', 'different', or 'undetermined'. Two photographs were defined as 'different' if three or more differences in coloration pattern could be detected. Instances where photograph quality, reflections, or abrasions prevented comparison over more than approximately 75% of the fish body were classified as 'undetermined'.

Stability

A school of sub-adult *S. javus* was held in the quarantine area of Underwater World Singapore (UWS) and was monitored over time. Throughout the study, a total of 12 animals were fin-clipped in different combinations in the posterior part of the anal, dorsal, and caudal fins for individual recognition within a common tank. The total length of each fish was also measured. In contrast, only four adult *S. guttatus* were available in a large exhibit at UWS. All photographs were taken with minimal interference, i.e. by patiently waiting outside the tank for the animals to swim by. Only photographs approximately at a right angle from the body surface were selected.

Comparing two photographs from the same side and individual, the number of changes was recorded. Splits, fusions, appearances, or disappearances of dots or lines were all treated identically. Right-sided and left-sided photographs were analyzed separately.

Siganus javus

Changes over hours: Seven animals were monitored over eight hours of a day to check for short-term changes in coloration patterns. They were photographed on both sides within 30 minutes, at 8am, 10am, 12noon, 2pm, and 4pm. This experiment was repeated on four days (September 19, October 17 and 24, and November 7, 2007). Photographs were manually compared to detect any changes over two-, four-, six-, and eight-hour intervals.

Changes over days: Similarly, photographs from 23 days were used to examine the variation in coloration patterns of 12 animals over one to six days.

Changes over weeks: Photographs from October 24, 2007 were compared to photographs taken one, two, three, four, and five weeks later. A total of 11 fish were monitored in this way.

Assuming that changes in coloration patterns occur gradually and at a constant rate over weeks, averaging changes over several consecutive equal time periods is more representative for a particular side of a fish. For the different weekly intervals (i.e. one- to five-weekly), non-overlapping intervals were compared and averaged to represent the rate of change.

Long-term changes: Photographs of six fish on each side were available for comparisons over the two months from September 27, 2007 to November 28, 2007 (62 days). Only a single fish was monitored over more than two months. The photo series of this animal covered 161 and 168 days on the right and left side, respectively. It was used to track changes and document their appearance on a time scale.

Siganus guttatus

Four *S. guttatus* were photographed at irregular time intervals from September 4, 2007 to May 5, 2008 (244 days; approximately 8 months). The best photographs taken on the first and last day of observation were compared to determine changes that may have appeared on each side of each fish. The photo series were examined to determine the first appearance of each change.

Statistical analysis

Working with count data, errors are not normally distributed and therefore, two samples were compared with the non-parametric Wilcoxon rank sum test (Crawley 2005). Program R was used to conduct the analysis (The R Foundation for Statistical Computing 2007).

Results

Individuality

The relation of six (0.03%) and nine (0.05%) comparisons of *S. javus* on the right and left side, respectively, could not be determined due to photograph quality, reflections or abrasions. No comparison resulted in an 'identical' result (Fig. 1). Every comparison of *S. guttatus* was found to be different (Fig. 1). All 189 individual *S. javus* and all 34 individual *S. guttatus* differed in their coloration patterns on their right and left sides.

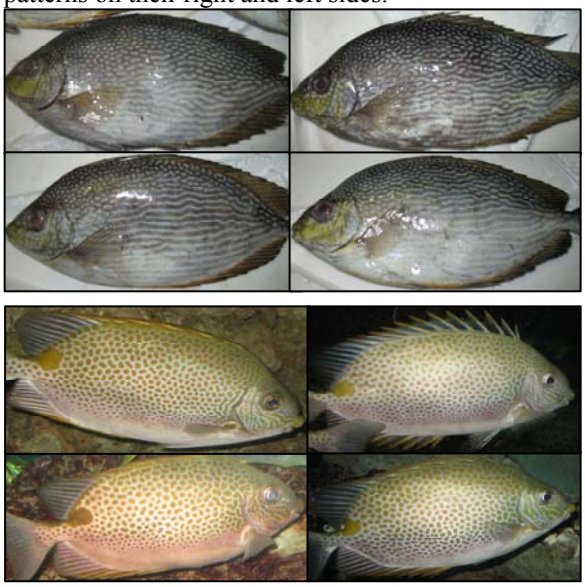

Figure 1: Examples for distinctively different coloration patterns of *S. javus* (top) and *S. guttatus* (bottom). Differences in *S. javus* were most evident at the posterior part below the dorsal fin, while differences in *S. guttatus* were more distinctive behind the gill cover.

Stability

Changes in coloration pattern occurred gradually over time (Fig. 2). They occurred faster in sub-adult *S. javus* than in adult *S. guttatus*.

Siganus javus

Fish were sized from 14 cm to 19 cm at the time of fin-clipping. The first differences in coloration patterns of *S. javus* occurred in weekly intervals. No changes were observed within time intervals of less than one week.

Changes over weeks: Within all one- to five-weekly intervals only three out of 12 fish showed some changes. Over one-, two-, and three-weekly intervals no more than a single change per side and fish was observed. A maximum of two changes per side and per fish was found in four- and five-weekly intervals.

The number of changes observed on the right and left sides were not significantly different ($p > 0.3404$). Single measurements from the same date and averaged measurements from consecutive intervals showed similar results for one- to five-weekly periods ($p > 0.1675$). The number of changes was not significantly different from zero ($p > 0.3458$).

Long-term changes: Over two months, only two out of six fish accounted for all eight changes (one fish had two changes per side, the other one showed four changes on the right side). The numbers of changes were not significantly different from zero ($p > 0.3711$), and did not differ between the right and the left sides ($p = 0.5271$).

Over longer intervals, 16 differences on the right side over 161 days and 13 differences on the left side over 168 days were recorded from a single *S. javus* monitored. Averaged over approximately 5.5 months, this corresponded to a monthly changing rate of 2.9 and 2.4 changes per month (CPM) on the right and left sides, respectively. Changes gradually accumulated over time.

Despite the changes, individual *S. javus* could easily be recognized after two months, including the side of one fish that underwent four changes. However, after 161 and 168 days (app. 5.5 months) on the right and left sides, respectively, discrepancies made recognition less easy, i.e. manual matching would most likely have failed on the right side.

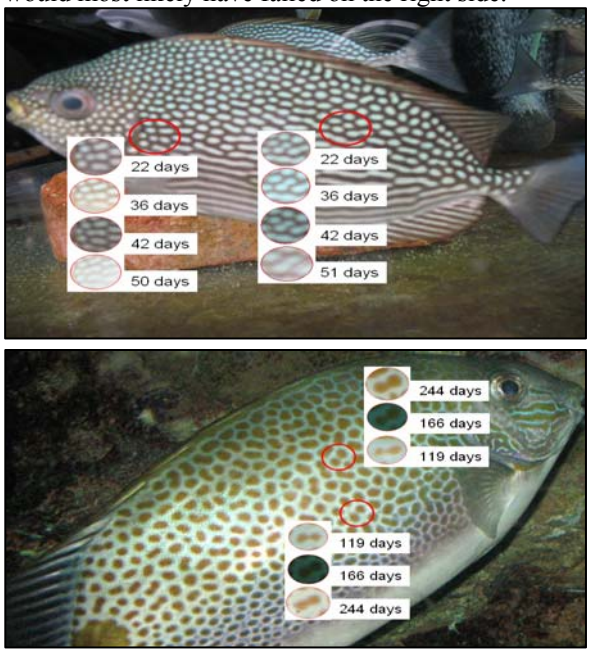

Figure 2: Gradual splitting dots in *S. javus* (top) and *S. guttatus* (bottom). The number next to the circles indicates how many days earlier the picture of this section was taken. Note that the splitting process was much faster in the sub-adult *S. javus* compared to the adult *S. guttatus*.

Siganus guttatus

On the right and left side, the four animals experienced on average 3.5 and 2.75 changes, respectively, over the 244-day observation period.

This was equivalent to 0.4 and 0.3 CPM. Early in the observation period, one fish obtained a superficial scratch on the right side, which healed in the time course of the study. The pattern at the location of the scratch remained largely unchanged. Only one dot stretched into a short line. Over the entire period, all four animals could very easily and unequivocally be recognized through photographs of both sides. The number of changes on the right and left sides were not significantly different ($p = 1$).

Discussion

Coloration patterns as individual identifiers

According to intuitive expectations, neither *S. javus* nor *S. guttatus* showed symmetrical coloration patterns. Consequently, photographs taken from the right and left side of an individual failed to match and the two datasets had to be treated separately in mark-recapture studies. Schwarz C. J. (pers. comm.) suggested treating the two datasets as independent sampling methods of the same population.

With no similar coloration pattern found twice within both sides of both species, the data suggests that twin-patterns can be practically excluded. This supports the intuitive assumption taken by many researchers when applying photo-ID: every animal has unique coloration, markings, and features. However, results should not be over-weighted. These schooling fish species occur in large parts of South-East Asia (*S. guttatus*) and, for *S. javus*, stretches as far as Australia and the Persian Gulf (Woodland, 1990). The sample sizes of 34 and 189 specimens of *S. guttatus* and *S. javus* used in this study, respectively, make up a very small sample to consider. Nevertheless, it seems reasonable to assume that twin-patterns do not occur in significant numbers in populations of *S. javus* and *S. guttatus*.

Stability of coloration patterns

Intuitively, one would anticipate coloration patterns to change gradually in relation to growth rates, i.e. patterns are expected to change equally on both sides of the animal and to do so mostly during fast growing stages of the life cycle. Stages with little or no growth are believed to exhibit very stable coloration patterns.

The results of this study support this intuitive theory. Changes occurred gradually and in equal quantities on the right and left side in both species. Assuming that *S. javus* and *S. guttatus* both follow the Von Bertalanffy growth curve, which a majority of marine organisms do (e.g. many elasmobranches; Cailliet et al., 1992; van Dykhuizen and Mollet, 1992; Acanthuridae; Choat and Axe, 1996; Scaridae; Choat et al., 1996), juveniles and sub-adults would be expected to grow fast compared to adults. If changing rates are indeed positively correlated to growth rates, coloration patterns would be expected to also change faster in small fish. According to Woodland (1990), *S. javus* commonly measure less than 30 cm standard length (SL), but they can grow considerably larger. With a maximum of 19 cm total length (TL), the fish used in this study are thus believed to reflect the sub-adult, fast-changing part of the life cycle.

In contrast, the four *S. guttatus* at UWS were fully-grown adults. They have been kept for at least one year prior to the start of the observations (pers. obs.). Although no measurement could be taken, animals were estimated to be close to 30 cm SL in July 2007. With a maximal SL of 35 cm reported by Woodland (1990), it is reasonable to assume that the animals at UWS represent the slow-growing and thus, the slow-changing phase of their life cycle.

In accordance with the intuitive theory, the sub-adult *S. javus* monitored over more than five months showed a much larger change in coloration pattern than did *S. guttatus* over eight months. With 2.9 changes per month (CPM) on the right side and 2.4 CPM on the left side *S. javus* changed at a much faster rate than *S. guttatus*, which averaged 0.4 and 0.3 CPM on the right and left side, respectively. After five months, *S. javus* could no longer be unambiguously identified, while *S. guttatus* were easily recognized even after eight months.

Although growth pattern and changing rates are not generally comparable among different species, they can be assumed to be similar in the two species of interest here. Both species show many anatomical similarities such as spine arrangement, jaw structure, and fright pattern (Woodland, 1990). They both grow to a comparable size, and have similar patterns consisting of dots and lines (Woodland, 1990). Furthermore, they are genetically very closely related (Lemer et al. 2006).

The results from sub-adult *S. javus* suggest that patterns only remain entirely stable on a very short time scale. After six days, changes started to occur in some fish, but animals remained easily recognizable even after two months, with up to four discrepancies per side. Therefore, photo-ID can be reliably used on *S. javus* up to 62 days. The fact that the number of changes was not significantly different from zero over all time intervals up to two months supports this conclusion.

The two-month reliability for photo-ID of sub-adult *S. javus* is a conservative estimation. The single fish monitored for a longer period showed only six changes after 134 days on the left side. Over both intervals, it was still possible to identify the two photographs as taken from the same individual, suggesting that photo-ID could also be used over time periods of up to four months. Likewise, the right side

remained easily identifiable over 127 days despite 13 changes. Identification of individuals on both sides only became difficult after more than a five-month interval.

In contrast, the adult *S. guttatus* exhibited much more stable coloration patterns. After the entire observation period of 244 days (app. 8 months), only very few changes occurred. All animals remained unmistakably identifiable. Thus, mark-recapture studies using photo-ID can be reliably used on adult *S. guttatus* over at least eight months.

To apply these results mechanically to all populations of *S. javus* and *S. guttatus* and its members may lead to inaccuracies. The two-month stability observed in sub-adults of *S. javus* is likely to be a more accurate estimate for sub-adult *S. guttatus* than the eight-month stability determined for adult *S. guttatus*. Identification of a sub-adult, presumably fast-growing *S. guttatus* after eight months is likely to fail and thus may lead to unrepresentative data. Similarly, adult *S. javus* may exhibit a stable pattern similar to that of adult *S. guttatus*.

The reliable identification intervals found in this study contrast with conventional tagging. The latter is often marked by a high rate of tag loss and tagging induced mortality shortly after release, followed by a period of lower loss rates (Thorsteinsson 2002). In contrast, coloration patterns are not lost and change only gradually. Thus, photo-ID studies are most reliable directly after the initial photographic capture and can potentially generate more accurate data in this regard.

Extraction of encounter histories from photographs is a tedious process, a disadvantage compared to physical tagging. However, the use of new software can accelerate the comparison of photographs (Speed et al. 2007; van Tienhoven et al. 2007). Furthermore, photo-ID is preferable when capturing live animals is difficult or when mortality rates have to be kept at zero (e.g. for species at risk).

While it is relatively easy to conduct photo-ID studies in captivity, obtaining photographs in the wild may pose a problem for non territorial and schooling fishes. However, photo-ID was still successfully used by the author to estimate short-term site-fidelity and localized population sizes of *S. guttatus* and *S. javus*. Territorial non schooling fishes (i.e. many Serranidae) promise more extensive applications of photo-ID.

In conclusion, the data suggests that photographs of individual sub-adult *S. javus* and adult *S. guttatus* can be reliably recognized over at least two and eight months, respectively. Within these conservative limits, photo-ID is believed to yield very accurate results for the two species: *S. javus* and *S. guttatus*.

Management of the aquarium fishery in the Republic of the Maldives

M. Saleem[1], F. Islam[1]

1) Marine Research Centre, Male', Republic of Maldives

Abstract. The marine aquarium trade of Maldives started around 1979 when most of the exports were sent to Sri Lanka. As the fishery matured, Europe became the major destination as the earnings related to quantity shipped increased. In 2007, there were seven registered companies, trading approximately 140 species of fish and 5 species of invertebrates. The contribution of the marine aquarium trade to the total value of marine exports is 0.55% and worth US$590,530 in 2007. The Maldives is a popular destination for snorkelers and divers and the collection of aquarium could impact dive tourism. Presently, a species based quota system is in effect that is derived from export data from the Maldives Customs Services, knowledge of the abundance of each species and knowledge of its tolerance to captivity. Random checks of the fish exports are scheduled for implementation following the introduction of a fish guide software. There are no specifically designated areas for collection of aquarium fish and the collection moved from one area to another as stocks declined. This pattern of resource use may act as indirect time area closures and aid in the replenishment of fish stocks. The last aquarium fish stock assessment survey was performed this year.

Key words: Economic value, ornamental fish trade, MPA

Introduction

The marine aquarium trade of Maldives is believed to have started around 1979 (Adam 1996). During the early years most exports were to Sri Lanka (Edwards and Shepherd 1992), and over the years the fishery has expanded, Europe becoming the major destination. In 2007, there were 7 registered companies, trading a total of about 140 species of fish and 5 species of invertebrates. Export of corals is banned in the Maldives and thus the trade does not include coral species. The only exception to this ban is the export of organ pipe coral (*Tubipora musica*), a species which is not traded in the aquarium fishery but nonetheless exported for pharmaceutical purposes, mainly to India.

Only a few species in the aquarium trade are directly exploited for other purposes, and aquarium species are probably the highest value-added product that is collected from coral reefs (Wabnitz et al. 2003). In 2007, 358,378 fish and invertebrates were exported from the Maldives, earning a total of Rf 7,529,266 (US$590,530) and making up 0.55% of total value of marine exports. Although the numbers of fish taken are relatively small, there is a potential for conflict of interest between the fishery and tourism, the major source of foreign exchange earnings. Tourism in the Maldives is essentially marine based and therefore heavily dependent on the rich diversity of this environment. The species that are collected by the aquarium trade are also an important attraction for tourists who visit the Maldives. As collection of fish is allowed on many of the tourist dive sites, there is the possibility of the two activities occurring simultaneously, thus increasing the conflict. Until recently, a few minor bait species were collected for the aquarium trade. Live baitfish is required by the pole and line tuna fishery, the primary fishery of Maldives. Juveniles of some species of edible reef fish such as *Variola louti* (Lunar tailed grouper) and *Cephalopholis miniata* (Vermillion rock cod) which are eaten locally or targets of the live food fish trade are also collected by the aquarium fishery. However, the quantity exported through this trade is insignificant compared to the amount landed at the fish market or exported as live food fish. For example, 23 juveniles of *C. miniata* and none of *V. louti* were exported in the aquarium trade between May and September of 2003. During the same period, 11,888 individuals of *C. miniata* and 12,992 of *V. louti* were exported in the live food fish trade (MRC unpublished data, 2003).

Due to such matters, along with concern of potential ecological and environmental impacts arising from the fishery, the Government of Maldives has closely monitored the trade since its inception (Adam 1996). In 1988, a blanket quota of 100,000 was set for maximum total number of exports of all species of fishes by Maldives Customs Services in consultation with the Marine Research Section (currently named Marine Research Centre) (Edwards 1988). While such

a quota system is simple and could be easily enforced, it could also lead to overexploitation of sought after species even when total exports are below the blanket-quota level, especially since about 20 species makes up about 70% of the trade (Edwards and Shepherd 1992). Thus, a provisional species based quota system was adopted for 22 species (Edwards and Shepherd 1992) but adherence and enforcement was lacking. More recently a species-based quota system for the majority of the species traded has been implemented. This has strengthened monitoring of the trade and aided management of the fishery.

Material and Methods

The data for this report was obtained from export information collected by Maldives Customs Services (MCS). The quantity of fish exported and the revenue derived each year is compiled by MCS. The trend in exported quantity and value of exports was obtained using the MCS information. The species data was compiled from 286 proforma sheets filled out by the exporters. This data set was not complete but gave quite a clear representation of the total exports.

Interviews were carried out with managerial staff of the two major exporting companies to investigate the processes involved in the trade, management issues and to identify difficulties with data collection. Information on the process of fish and invertebrate collection was gathered during a field visit to the aquarium of the largest exporting company, Sub Tropical Exotic Paragon (STEP) in 2000 and subsequently in 2004 and 2008. Fish collectors and staff of the aquarium were interviewed during these visits.

Status of the Trade

Over the years, the fishery fluctuated with Europe becoming the major destination (Figure 1). In 2007, there were seven licensed companies in the aquarium trade. However, 54% of the exports were by one company, earning 66% of the total revenue. Approximately 90 people are employed in the trade of which only a small number are expatriates working in the managerial and administrative positions. This is in contrast to the mid-90s when majority of the work force were Sri Lankans working essentially as divers (Adam 1996). This transformation was probably due to enforcement of Clause 14 of the Fisheries Law (Law No. 5/87) which states that only Maldivians have the right to carry out fishing activities in the fishing grounds most commonly used by Maldivian fishermen, which represents an area within 75 miles of the outer atoll rim. This was triggered as a consequence of the increasing use of moxy nets, a destructive method of fishing which was introduced to the fishery by the Sri Lankan divers (Adam 1996).

Species Based Quotas

The species-based quota system that is in effect at present was based on MCS export data and on general information of species such as rarity in the natural environment, as well as tolerance of species to captivity. Such a selective quota system is difficult to establish, as information on population characteristics such as abundance and boundaries of habitats in collection areas and species densities is required to understand maximum sustainable yields, and to identify those species that are susceptible to overexploitation.

There are three categories adopted in this system. Category A includes 17 individual species that are banned from export. Category B includes 66 species that are subject to an export quota. Category A includes species that do not survive well in captivity such as *Chaetodon meyeri, C. trifasciatus* and *C. triangulum* (Wood 1985) and those that are locally rare like the Armitage's angelfish (*Apolemichthys armitagei*). In addition to Category A listed species, it is an offence to export any species of parrot fishes, puffer fishes, porcupine fishes, eels or giant clams. Category B include species from families Pomacanthidae, Ephippidae, Ostraciidae, several Chaetodontidae and Pomacentridae, Cirrithidae, Monacanthidae, Serranidae, several Labridae, Balistidae, Plesiopidae and Scorpaenidae. Category C which consist of 71 species that can be freely exported up to a maximum total number of 300,000 individuals. There is also a ban on exporting any species utilized as live bait in the pole and line tuna fishery. In compliance with this regulation, the most traded species globally, *Chromis viridis* (Blue-green damselfish) (Wabnitz et al. 2003), is not exported from Maldives.

The current system appears to be quite effective, although there are still some difficulties in monitoring the trade. The system was administered through the use of proforma aquarium fish export forms as

recommended by Edwards and Shepherd (1992). The form lists species' scientific and common names that are commonly exported in the trade. It also allocates a code name to each species and the exporters fill out one proforma sheet per consignment. The problem with this system lies in effectively monitoring the quotas as there are different agencies involved in the process. While the Marine Research Centre (MRC) sets the quotas, Ministry of Economic Development and Trade (MTI) issues export licenses and MCS collects the proforma sheets filled out by the exporting companies. MCS compiles data summaries such as quantity of fish and revenue from each consignment as well as the destination and dates.

Copies of these sheets are forwarded to MRC where the species data is compiled. Thus clarity of responsibilities with regards to monitoring quota balances is lacking. As a result, every year a few species in Category B are exported in access of the quotas set for these species. Although infrequent, a few individuals in Category A are also exported occasionally.

Another problem is the use of a wide variety of common names to identify the different species. It is not clear how reliable the data collected from the proforma export forms is. One of the exporting companies reported that they were not very familiar with the species names and therefore were not very confident when filling out the proforma sheets.

Nonetheless, in the absence of species catch and effort data, the species based quota system provides reliable estimates of the trade including numbers of fish exported, revenue derived from the trade, destinations, species data and unit prices.

Licensing scheme

The mandate to regulate the export trade lies within the Ministry of Economic Development and Trade (MEDT). They are responsible for issuing export licenses to the aquarium fish exporting companies and this license is based on the export value, which is determined by the exporter. The minimum value is Rf 100 (Rf12.75 =US$1.00) and there is no upper limit for the maximum value. There is a 0.1% tax on the value of the exported fishes. The quota for Category B species is determined by MRC for the year and is divided up, and a part is given out under the license. The license is valid until the last day of the year it was issued. As the license is based on the value of the exports, once the license value is reached, it has to be renewed even though some export quota is remaining under that particular license. If a species has been exported up to the quota issued with the license, the quota is renewed provided that the overall yearly quota set for that species by MRC is still remaining.

A major problem with a value based licensing system can be under quoting of prices of fish by exporting companies in an attempt to maximize the number of fish exported per license. This would have consequences on the assessments of the annual revenue from the fishery as well as average unit prices. Thus the present system of licensing should be eliminated and a quota based system put in its place. For this to be achieved, all species traded in the industry need to be given a yearly quota including those in Category C.

Collection areas

Aquarium fish collection can be carried out on any reef except resort house reefs and the 25 protected dive sites which were established in 1995 and 1999. In the beginning, collection areas were concentrated around Male' due to the dependence of the trade on an international airport, with direct flights to Europe and other destinations (Edwards and Shepherd 1992). With the establishment of regional airports in the northern and southern atolls and the introduction of faster boats, collection has spread to other atolls including Baa in the north, Male and Vaavu atolls in the central region and Gaafu Alifu and Gaafu Dhaalu in the south (Fig. 2).

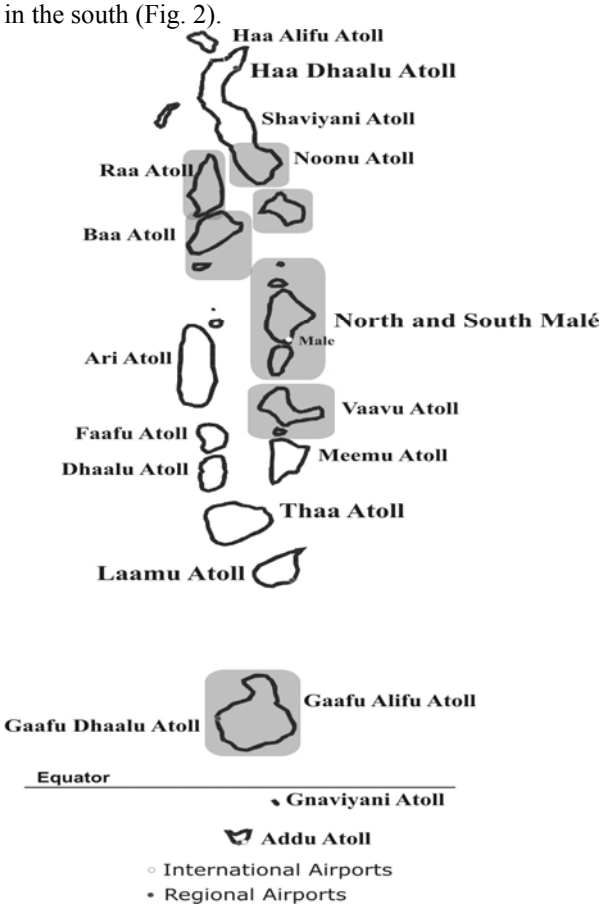

Figure 2: Map of the Maldives showing areas of collection 2008 (shaded areas)

The collected fish are brought by domestic planes and speed boats to the holding facilities in Male' atoll and conditioned before sending them abroad. A maximum of 50 l of fuel is used per day on the boat to get to collection sites and return to base. This suggests that collection is carried out in an estimated area that can be reached within a 1 hr boat ride.

There have been changes in collection areas over time. In 2000, collection was carried out in Haa Dhaalu, Male', Laamu and Thaa atolls while the collection areas were in Baa, Male' and Vaavu atolls in 2004. More recently collection occurs in Noonu, Raa, Baa, Lhaviyani, Male', Vaavu and Gaafu Alif and Gaafu Dhaalu atolls. This pattern of resource use may act as temporary area closures and aid in the replenishment of fish stocks.

At present there are no designated areas for collection of aquarium specimens. From a scientific point of view it is very important to have designated areas for collecting aquarium fish. Edwards and Shepherd (1988) recommends a fishing area of 20% and the remaining 80% closed to fishing, thus acting as marine reserves. Such a system would ensure that a recruiting stock is available to replenish the fished areas, minimizing overexploitation (Palumbi 2003) and extinction of sought after species. In the past few decades, marine reserves have been advocated as a tool to replenish overexploited stocks of species targeted by food fisheries (Russ and Alcala 1996, MacClanahan and Mangi 2000). A study carried out in Hawaii on aquarium fish collection and marine reserves found that aquarium fish increased in newly established Fishery Replenishment Areas (FRAs) while there was a significant decrease in those areas open to collection (Tissot et al. 2002). These two sets of sites were compared to control sites for evaluation of effectiveness of FRAs in management of the aquarium fishery.

Awareness initiatives

A guide to fish identification was prepared by MRC in 1996 to aid those involved in the fishery, including Customs officials, fish collectors and managerial staff. More recently an online fish guide has been developed to aid with fish identification and strengthen monitoring. It is hoped that better informed people will yield more accurate data filled out by the exporters. In addition to the guide, workshops are being held for exporters and MCS officials involved in the trade to increase awareness of the fishery and to provide information on strengthening data collection and monitoring. Workshops introducing the fish guide are being planned for this year and the first of the series was held in September 2008 for the MCS officials. Similar workshops will be held for the exporter and the staff of the Ministry of Economic Development and Trade later in the year.

Licensing and data analysis

An important component of monitoring and regulating the trade is to carry out regular reviews of the data, to assess trends and to assess whether existing levels of exploitation are sustainable. An example is the case of the poison goby and the long nose filefish. Disappearance of these species was not detected until a review was done in 2000, two years after the bleaching event. This could have been avoided if the species data are regularly analysed.

At present, quotas are given out to the exporters by MEDT. The exporters are required to present the relevant license with each consignment. MCS keeps tally of the numbers of each species exported to ensure that fish are not exported beyond the quotas given under that particular license. However, in 2002, eight species in Category B were exported beyond their respective quotas. This can be avoided through frequent analysis of species data from the proforma sheets, which would show if the export numbers are approaching quotas set for the year. MRC could play a larger role in monitoring quotas using data from the proforma sheets. However, the data transfer process between MRC, MEDT and MCS needs to be strengthened to make sure that all information is available to MRC in a timely manner in order to carry out the analysis.

Resource Assessment Survey

A resource assessment survey of selected species in the B Category of the quota list was carried out in June 2008. Impact and control sites were selected in Baa Atoll, North and South Male' Atolls and Vaavu Atoll. Timed swims were employed to estimate abundances of fish species while reef resilience techniques were used to assess the status of the habitat and the benthic environment. Results of the survey are expected to be available in August 2008. This survey was carried out to re-assess the quotas allocated for the different species. As the present quotas were based on information from only Male' atoll and since collection has spread to the outer atolls, it was felt that quotas for some species could be adjusted depending on their resource status.

Recommendations

The following recommendations are based on our observations and analysis:

- Establish designated areas for collection of fish for the aquarium trade
- Increase consistency of names used by exporters, collectors, clients and the government agencies

- Introduce daily log books to obtain information on collection areas, hours spent on collection, mortality of fish
- Develop a code of conduct for fish collectors
- Develop criteria or acceptable standards for holding facilities
- Develop criteria for providing certification to exporters from the government
- Carry out a stock assessment of the species exported in the aquarium trade
- Strengthen monitoring of the exports and regulation of the trade through increasing transparency of responsibilities of the different agencies involved in the trade
- Set quotas for all species traded including those in Category C
- Substitute the present system of value based licensing with quota based licenses.

Acknowledgement
Marine Research Centre of the Ministry of Fisheries, Agriculture and Marine Resources supported this research. The Atoll Ecosystem Conservation (AEC) Project funded my travel and accommodation expenses to the 11ICRS. A very big thanks to Shahaama Abdul Sattar, Dr. Mohamed Shiham Adam and all at MRC who helped out in the study. A special thanks to the export staff at Maldives Customs Services, the staff of Statistics section at MoFAMR and Ahmed Fazeeh of Subtropical Exotic Paragon for their cooperation and for all the information provided for this study. Last but not least, I express my gratitude to Dr. Norman Quinn who encouraged me to publish this paper and helped me with review, layout and formatting.

Reef Fish Spawning Aggregations in the Bay of Bengal: Awareness and Occurrence

J. Tamelander*, S. Sattar, S. Campbell, V. Hoon, R. Arthur, E.J.K. Patterson, U. Satapoomin, M. Chandi, A. Rajasuriya and M. Samoilys

*IUCN, P.O.Box 13513, Dar es salaam, Tanzania

Abstract. Reef fish spawning aggregations are highly vulnerable to over exploitation. Little research has focused on spawning aggregations in the Bay of Bengal. Interview surveys were conducted among fishers in India, Indonesia, Maldives, Sri Lanka and Thailand in order to determine the level of awareness of spawning aggregations, to identify aggregation sites and species, and to assess fishing pressure on and status of spawning aggregations. Results show low awareness of spawning aggregations throughout the region except in the Maldives where fishers relying on visually aided hook-and-line line fishing reported in-water observation. 91 spawning aggregation sites corroborated by several fishers were identified in four atolls in the Maldives, including those of *Epinephelus fuscoguttatus, E. lanceolatus*, *E. polyphekadion*, *Plectropomus areolatus, P. pessuliferus* and *Lutjanus bohar*. This is the first record of spawning aggregations of *P. pessuliferus.* The spawning aggregations are fished, and the growing grouper fishery will require a precautionary management approach. Increasing awareness among managers and policy makers as well as fishers of the ecological significance and vulnerability of reef fish spawning aggregations remains a high priority.

Key Words: coral reef, reef fish, spawning aggregation, reproduction, Bay of Bengal, South Asia

Introduction

Many species from several families of reef fish spawn in aggregations, including some groupers, snappers, parrotfish and rabbitfish (Claydon 2004, Cornish 2005). A common definition of a spawning aggregation is "a group of conspecific fish gathered for the purpose of spawning with fish densities significantly higher than those found in the area of spawning during the non-reproductive periods" (Domeier and Colin 1997, Colin et al., 2003). Domeier and Colin (1997) propose there are two types of spawning aggregations: 'resident' and 'transient', the former generally occurring within the home range of fish that aggregate frequently and throughout the year. The latter may take place at only a specific time of a month once or several times a year, and fish may migrate hundreds of kilometers to an aggregation site (e.g. Bolden 2000). Transient spawning aggregations may represent up to 100% of a species' reproductive output (Domeier and Colin 1997). The larvae from aggregations may travel far before settling out of the plankton to mature. Thus spawning aggregations can supply seed for fish populations over very large areas.

As spawning aggregation sites and timings tend to be consistent, they are often known to communities with a long history of and high reliance on fishing. While subsistence fishing of spawning aggregations may be sustainable in the long-term, such as has been the case in parts of the Pacific Ocean (Johannes 1981), they can easily become over exploited (Sadovy and Domeier 2005). Persistent fishing may cause spawning aggregations to cease, leading to dramatic declines in a species' population (Sala et al. 2001, Aguilar-Perera 2006). Groupers, many of which aggregate to spawn and are long lived with late maturity, are particularly vulnerable to over-fishing (Sadovy 1996, Dulvy et al 2003). However, with adequate protection, spawning aggregations that have been severely overharvested can recover (Beets and Friedlander 1998). Careful management of reef fish spawning aggregations is thus critical to both the health of fish populations and the coral reef ecosystem, as well as to communities that depend on fishing (Domeier et al 2002, Sadovy and Domeier 2005), and should be, but are rarely, considered in Marine Protected Area (MPA) design (Robinson et al 2008).

There is a limited but growing body of scientific literature on reef fish spawning aggregations, and the Society for the Conservation of Reef Fish Aggregations (SCRFA, www.scrfa.org) maintains an online database of spawning aggregations (Cornish 2005, Sadovy et al. 2008). Reef fish spawning aggregations have been documented to some extent in the Western Indian Ocean (Robinson et al. 2004, Samoilys et al. 2006, Robinson et al. 2008) as well as in Indonesia (e.g. Pet et al. 2005), but little published

information exists on reef fish spawning aggregations in South Asia and around the Bay of Bengal, except some detailed studies from one atoll in the Maldives (Sluka 2001 a,b). Even anecdotal information is scarce. Consequently both fisheries and MPA management in the region remains constrained by a shortage of data as well as awareness among management institutions.

Many species known to form spawning aggregations elsewhere are important resource species around the Bay of Bengal, including several groupers, snappers and trevallies. For example, the Maldives has a well-developed, widespread and unregulated reef fishery serving the tourist resorts in the country. There is also a specific grouper export fishery which although regulated is in decline (Sattar and Adam 2005). A grouper fishery is developing fast in the Lakshadweep Islands, India (Tamelander and Hoon 2008, Arthur 2008), and is already well established in the Andaman Islands and in Aceh, Indonesia. Many resource species in the Gulf of Mannar are threatened by destructive fishing and overfishing (Bakus et al 2000).

In view of critical knowledge gaps with respect to fish spawning aggregations in the Bay of Bengal as well as present reef fishery trends, a survey was conducted to identify potential reef fish spawning aggregation locations, species and timings, and determine levels of knowledge of them among fishers.

Materials and Methods

The study was carried out through interview surveys with fishers. Interviews were conducted by field teams familiar with the target areas and with experience of community based research. Interviewers also received training at a regional workshop prior to the surveys. Key informants in fishing communities were targeted, including fishers using a variety of gears and of varying age and experience. A questionnaire based on guidance from SCRFA (Colin et al 2003) and previous surveys in the Indian Ocean (Robinson et al 2004, Samoilys et al 2006) was used. The questionnaire contained questions on personal information (age, years fishing, gear, areas visited etc.); knowledge of occurrence of reef fish spawning aggregations (have aggregations been observed, what appears to be the reason for aggregating, what are the spatial and temporal characteristics etc.); and what species are known to form spawning aggregations. Pictures, including of fish species and hydrated gonads, were used to accompany the questionnaire. In cases where spawning aggregations were known the interview went on to detail habitat, depth, time (month, lunar phase, time of day), as well as fishing pressure, estimated catches and catch per unit effort. The reliability of interviewees was subjectively assessed based on responses provided, including knowledge of the local environment and fish species as well as years of experience, and rated 'high' or 'low'.

Sites, Time and Sampling Effort

Surveys were carried out between March and October 2007, focusing on important reef areas with known reef fisheries in five countries (Fig. 1):

- Maldives: Baa, Dhaalu, Faafu and Vaavu Atolls (56 interviews)
- India: Agatti and Minicoy in the Lakshadweep Islands (49 interviews), Mandapam and Keezhakkarai coast in the Gulf of Mannar (63 interviews), and informal discussions in the Andaman Islands;
- Indonesia: Weh Island in Aceh Province (60 interviews);
- Sri Lanka: informal discussions with fishers in south western and western reef areas;
- Thiland: Phuket Island, Phuket Province, and Bulon island group, Satun Province (190 interviews).

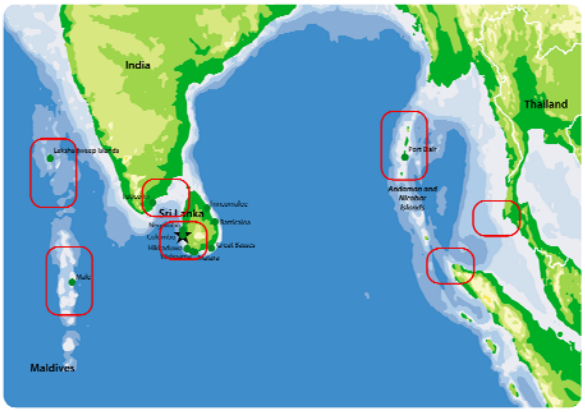

Fig. 1. Map of the region with target areas marked in red.

Data Analysis

Raw interview data were compiled and data from respondents with low reliability ranking and respondents not aware of spawning aggregations were removed. Data from reliable respondents was further queried to confirm potential spawning aggregations reported. Spawning aggregations were considered corroborated if the species and site were mentioned by at least two respondents, or if direct or indirect evidence was furbished, such as observation of spawning or reports of prevalence of hydrated gonads in catch at the time of an aggregation.

Results

Results from the survey are reported here except exact

locations and timings of spawning aggregations, which will not be made public due to the sensitivity of this knowledge. Results will be entered onto the SCRFA online database.

Maldives
Several spawning aggregations were identified in the Maldives, with 91 reported by 2 or more interviewees, 15 of which were reported by 9 or more, and one site reported by 17. Spawning aggregations were validated by reports of sighting of aggregations underwater, and/or enlarged gonads and release of eggs on capture. Fishers reported fish do not take bait when ready to spawn giving low catches during the first few days of an aggregation. .

Spawning aggregations of the following species were confirmed (number of respondents in brackets): *Epinephelus fuscoguttatus* (53)*; Epinephelus lanceolatus* (11); *Epinephelus polyphekadion* (4); *Plectropomus areolatus* (42); *Plectropomus pessuliferus* (11); *Lutjanus bohar* (6). Possible spawning aggregations of *Plectropomus laevis, Variola louti,* and *Caranx melampygus* were reported by one respondent each.

Aggregation depths ranged from several meters to over 50m in *E. fuscoguttatus* and *P. areolatus. E. fuscoguttatus, E. lanceolatus* and *P. areolatus* were reported to aggregate in the 3rd lunar quarter, *Plectropomus pessuliferus* during full moon. Aggregations reportedly tended to be largest during the inter-monsoon periods (April-May and November-December).

India
Fishers at Minicoy and Agatti in the Lakshadweep Islands had no information on reef fish spawning aggregations, although their knowledge of local ecological and environmental conditions is considerable. There were also no indications of spawning aggregations in the near-shore shallow coral areas of the Gulf of Mannar. Fishers reported aggregations of several species 5-10 miles offshore in rocky habitat at depths between 10 and 20m, but while opinions of species, timing, and lunar phase are shared among several fishers from different villages none of the respondents identified spawning as a reason for aggregating. Few interviews were carried out in the Andaman Islands and results are inconclusive. Most fishers were unaware of the phenomenon although there were suggestions of potential spawning aggregations of *Plectropomus* spp. in South Andaman.

Indonesia
Awareness of spawning aggregations was low, and a distinction between spawning and normal schooling was not made. However, although not corroborated, possible spawning aggregations of five species were reported from sites on the west, south and east coast of Weh Island at different times, dependent on location and species: *Bolbometopon muricatum*, *Cephalopholis miniata*, *Variola louti*, *Cheilinus undulatus*, and *Caranx lugubris*.

Sri Lanka
Informal discussions with fishers indicated no awareness of spawning aggregations in southern and western Sri Lanka.

Thailand
Some fishers reported fish aggregations in certain areas and at certain times, but while there was some agreement on aggregation timing, location and species, and while these are typical of spawning aggregations reported elsewhere, none of the interviewees mentioned spawning as the reason for aggregating.

Discussion
The results of the survey indicate that awareness of fish spawning aggregations among fishers in South Asia is low, with some notable exceptions. Possible reasons for this are manifold; we highlight the following:

- Few fishing methods involve fishers spending time in the water and directly observing reef fish. This is the case e.g. in Thailand (with the exception of indigenous sea gypsy communities), as well as in Aceh, the Lakshadweep Islands, Gulf of Mannar, and the Andaman Islands, where only some spear fishing is practiced, mainly in near shore and relatively shallow areas targeting octopi, lobster or reef fish. Spear fishing is more widely practiced in the Nicobar group of islands not covered by this survey. In Sri Lanka spear fishing using scuba and targeting groupers is common, but as the fishery is illegal fishers are reluctant to furbish information.
- Overfishing to a point where aggregations may have ceased, or at least been significantly reduced to densities hard to detect;
- Relatively low reliance on the demersal reef fish species that spawn in aggregations, as in Sri Lanka, where the Scombridae, Carangidae and Clupeidae make up a large part of fish landings (FAO 2006);
- Fish and fishing constitute supplements rather than the sole primary source of food and income in many communities particularly on the continental margin;
- Erosion of traditional knowledge, particularly in Lakshadweep, which in the 1960s and 70s saw a shift from reef fisheries to commercial tuna fishing as part

of a development programme. However, the reef fishery remains important for household consumption and many fishing methods are named after the target species, e.g. *Chammam fokkal*, "fishing for grouper" in Agatti (Hoon 2003).

The higher knowledge of reef fish spawning aggregations in the Maldives is a likely effect of the very high reliance on fisheries. While the pole and line tuna fishery has been the mainstay of the people over hundreds of years, coral reefs are used extensively for catching bait for the tuna fishery and reef fish have been a significant supplemental food source in many areas. The use of visually aided hook and line fishing for grouper means fishers spend long times in the water observing fish first hand. There was not a large difference in years of experience between fishers aware of spawning aggregations (49 interviewees, average 20 years of experience) and those not aware (seven interviewees, average 18 years of experience).

As the Maldives follows the Islamic lunar calendar, fishers are able to report lunar phase very accurately. Most respondents reported physical characteristics as the likely reason for spawning aggregations in a given location. Use of GPS among fishers is low; thus sites are defined by reef features and may in some instances be broad approximate areas, such as comparatively featureless reef slopes or sandy areas. Spawning aggregation depths estimated by fishers were dependent on visibility, and thus approximate. Fishers did not provide detailed information on tide and temperature. The tidal range in the area is modest, less than 1m, and temperatures very stable around 29-30, except in areas of localized upwelling.

Species

There is little information on spawning aggregations among the species identified in this study in Fishbase (Froese and Pauly 2008), while the SCRFA database includes records of confirmed spawning aggregations for most species reported here, including several records of *E. fuscoguttatus*, *E. polyphekadion, P. areolatus* from the Indo-Pacific; one record of *E. lanceolatus*, from Indonesia; a few records of *P. laevis*, *Cephalopholis miniata* and *Lutjanus bohar* from Papua New Guinea; some records of *Cheilinus undulatus* from Malaysia and Palau; and one record of *Caranx lugubris* reported from the Cayman Islands.

Three species for which potential spawning aggregations were recorded in this study are currently not included in the SCRFA database:

- *Plectropomus pessuliferus,* which is listed as a priority species for conservation due to its limited range, but not reported to form spawning aggregations (Domeier et al 2002).
- *Variola louti,* which may form spawning aggregations as indicated by observations from Papua New Guinea, with high densities including gravid females (Hamilton et al. 2005);
- *Caranx melampygus*, which is listed as forming spawning aggregations in Palau (Johannes 1981).

Aggregation spawning of *P. pessuliferus* is now confirmed in the Maldives. *C. melampygus* and *V. louti* were reported by only one respondent each in the Maldives, with unreliable reports of aggregation spawning of the latter in Aceh, and are thus not confirmed records.

Conclusions and Recommendations

While relatively limited in geographic scope and resolution, and while providing largely indicative results, this study is the first of its kind in the Bay of Bengal, and provides new information on indigenous knowledge of spawning behavior in high value reef fishes. Importantly, it also provides corroborated records of previously undocumented reef fish spawning aggregations in four atolls in the Maldives, including confirmation of aggregation spawning in one grouper previously not known to form spawning aggregations (*P. pessuliferus*).

The also provide useful information for fisheries management. One of the main threats to high value reef fish populations in the Bay of Bengal is the expanding market for chilled and live reef fish in East and Southeast Asia. A precautionary approach to settings export quotas as well as other restrictions could help prevent the overexploitation of fish spawning aggregations seen in Indonesia (Sadovy and Vincent 2002, Mous et al. 2000). A recent survey of grouper stocks in five atolls in the Maldives (MRC unpubl) confirms the decline in the fishery seen from export data (Sattar and Adam 2005), and fishers also reported reduced catches from spawning aggregations. Surveys in the Lakshadweep have shown that grouper diversity is relatively high and populations are recovering after what appears to be a reduction in abundance after the 1998 coral bleaching event (Arthur unpubl.). The *C. undulatus* density is representative of reefs with very low fishing pressure (Arthur unpubl., Sadovy et al. 2003). However, with continued demand, groupers, as well as other fish, are increasingly caught for cash income and export.

Further study is required to document in more detail spawning aggregations in the Bay of Bengal, at a higher resolution than in this initial survey. Such information is critical for fisheries as well as MPA

management planning. Sensitizing policy makers, managers and fishers regarding reef fish spawning aggregations, their conservation and management, remains a high priority for the region.

Abstract. Rising demand for coral reef resources worldwide has led to an active international trade in reef organisms that are sourced primarily from tropical developing countries. Although these trades tend to be lucrative, it is unclear what economic benefit flows to the exporting country. We use Fiji as a case study to quantify the economic benefits of trade in coral reef resources to local communities. The live rock and aquarium fish trades provide the highest net income to collectors. However, the financial benefits of these trades are limited to a few villages. On the other hand, the bêche-de-mer fishery returns lower incomes to participants, but since the fishery has a large geographical coverage, more people are able to participate and obtain financial benefits from it. We find that the coral reef associated export trades generally provide a supplementary, rather than primary, source of income. This indicates that coastal communities should engage in diversified livelihoods. The unsustainable impacts of the export trade on the coral reef ecosystem reinforce the need for communities to be adaptable. As many coastal communities tend to fall back on subsistence fishing when a niche fishery declines, there is a need to better manage the extraction of coral reef resources in order to ensure their sustainability.

Key words: coral reef export trade, Fiji, socio-economics

Introduction

Coral reef resources such as fishes, invertebrates, and corals have long supported subsistence and artisanal fisheries that sustain the dietary and livelihood needs of coastal communities throughout the developing tropics (McManus 1997). It is widely acknowledged that growing populations and coastal development have increased pressure, and in many cases, led to unsustainable use of coral reef ecosystems (Pauly 1993). At the same time, the situation is exacerbated by the lucrative international coral reef trade, which is, in most cases, centered in wealthier, developed regions of the world. Demand for certain reef species for the live reef food fish, aquarium, and Chinese traditional medicine trades, for example, has led to intensive fishing and collection of certain reef species such as groupers, sea cucumbers, seahorses, corals, and butterfly fishes. The negative ecological impacts of these trades have been well documented (Sadovy et al. 2003; Lunn and Moreau 2004; Martin-Smith and Vincent 2006; Scales et al. 2006; Vincent et al. 2007).

What is not as commonly addressed is the extent to which trade in coral reef resources provides economic benefits to the exporting society. We address this question by using Fiji as a case study to examine the benefits the coral reef resource trade provides to local Fijian communities. Specifically, we look at the spatial extent of the coral export trade, and participants' economic dependence on these trades.

Fiji is an archipelago made up of 844 islands, cays, and islets, of which 106 are inhabited (Vuki et al. 2000). This group of islands is situated in the South Pacific between 15-23°S and 177-178°W, with a terrestrial area of 18,500 km^2 and a coastline of 1,130 km (CIA 2007). With approximately 1,000 coral reefs supporting about 200 species of corals (Rowlands et al. 2005) and around 1,200 marine fish species (Vuki et al. 2000), Fijian society has traditionally relied heavily on marine resources for subsistence and livelihoods. Marine resources have also become valuable export commodities, with the fisheries sector, inclusive of both coastal and offshore resources, contributing about 2.5% to Fiji's total GDP (ADB 2005).

The trade in marine aquarium organisms includes ornamental fish, invertebrates, coral, and live rock, and has been active in Fiji since the early 1970s (Yeeting 2007). Pacific island nations supply about 18% of the 3.4 million ornamental fishes traded on the international market, with Fiji alone contributing

5% (Wabnitz et al. 2003). Similarly, Pacific island nations supply 25% of internationally traded live corals, with Fiji supplying 4% (Wabnitz et al. 2003). In particular, demand for live rock from Fiji has grown steadily since the late 1990s (Lal and Cerelala 2005), due to its distinctive colour, and Fiji is now one of the major exporters of live rock. Overall, Fiji is ranked fourth after Indonesia, China and the Philippines in the export of marine aquarium products globally (Lal and Cerelala 2005). There are five companies involved in the trade of aquarium products in Fiji. These companies operate in 25 *qoliqoli* (traditional fishing grounds) that are located along the Coral Coast and islands off the Western Division (Lal and Cerelala 2005).

The bêche-de-mer (sea cucumber) trade has a long history in Fiji dating back to the 1800s. This sector exhibits a 'boom and bust' cycle, with the most recent boom taking place in the mid 1980s when production of dried bêche-de-mer in Fiji peaked at an estimated 1,000 tonnes in 1988 (Adams 1992). The collection of bêche-de-mer is largely carried out on a small scale in villages throughout Fiji. Bêche-de-mer is gleaned from shallow reefs by men, women, and children, or collected by men during dive fishing trips. Bêche-de-mer is sold either raw or dried to middlemen. Closer to urban areas, villagers may travel to sell their product, whereas in more remote regions, middlemen make collection trips to the village several times per month. Alternatively, company agents are posted at a village, and are responsible for collecting and bringing the product to market. Middlemen themselves may be agents for an export company, or may export the product directly to overseas markets in China and North America, among others.

The live reef food fishery (LRFF) was established in Fiji in 1998, targeting coral groupers (*Plectropomus* spp.) for markets in Hong Kong and Southeast Asia. It reached a maximum of eight companies before declining to one or two in recent years. Like the aquarium trade, LRFF companies have to negotiate a contract with *qoliqoli* owners. These companies employ fishers from local villages, and use mother vessels to collect fish from locations around Vanua Levu, which are then brought to Nadi for export (Yeeting 2001; Ovasisi 2006).

Coral reef resources provide a valuable source of export revenue to Fiji. From 2002 to 2004, exports of aquarium products, live reef food fish, bêche-de-mer, and trochus shells generated between USD 10.8 and USD 13.7 million in annual export revenue per year (Table 1). In comparison, domestic sales of reef-associated finfish and invertebrates in 2004 were estimated to have a gross value of USD 33.4 million (Starkhouse 2009).

Table 1. Export value (USD)[a] of coral reef resources 2002-2004, extracted from Fiji Department of Fisheries Annual Reports

Reef resource	2002	2003	2004
Aquarium products[b]	5,535,135	6,540,541	6,486,486
LRFF[c]	972,973	572,973	154,184
Bêche-de-mer	5,945,946	2,702,703	4,324,324
Trochus	1,259,459	978,378	810,811
TOTAL	**13,713,514**	**10,794,595**	**11,775,805**

[a] The exchange rate on 31 January 2009 was 1 USD = 1.85 FJD.
[b] Includes ornamental fish, live rock, live coral, live invertebrates, live clams, and unworked corals.
[c] Data for 2003 and 2004 obtained from Ovasisi (2006).

Materials and Methods

We interviewed 47 fishers and 10 middlemen and reef resource export companies in May and June 2008. Our interview team included two research officers from the Fiji Fisheries Department. Interview sites were chosen to provide a wide geographical coverage of Fiji as well as being inclusive of both artisanal and subsistence fishing communities. Fishers were chosen opportunistically – in most cases, we interviewed fishers who were assembled at a central location at the request of the village headman, from whom we had obtained permission to conduct interviews at the particular village. These included full and part time fishers, both men and women.

The interviews followed a semi-structured format where a prepared questionnaire was used to guide the interview, but respondents were free to elaborate on issues of interest. Our interviews focused on the economic aspects of the live reef food fish and bêche-de-mer fisheries, including information on fishers' catch, revenues and costs.

Fisher interviews were conducted in 13 villages and settlements in western and northern Viti Levu, the Yasawa islands, Bua Province in Vanua Levu, and Kadavu island south of Viti Levu. Interviews with middlemen and traders took place in major towns such as Suva, Lautoka, and Labasa. Published and grey literature, and statistics from the Fisheries Department Annual Reports and Secretariat of the Pacific Community were used to provide national level information on the aquarium, coral, and live rock trades.

Results

Spatial coverage and participation

The bêche-de-mer trade was the most geographically dispersed (Fig. 1), and involved the most number of participants as it is harvested by both adults and children in coastal villagers throughout Fiji. Fifty-one

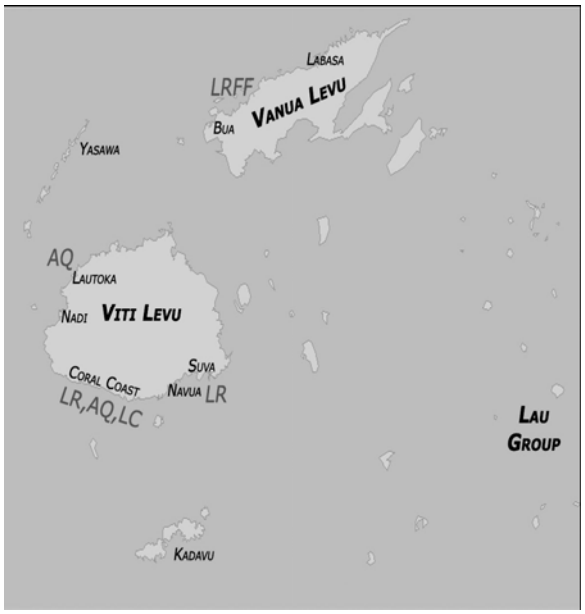

Figure 1: Map showing the spatial extent of the coral reef export trades. Note that there is no indicator for the bêche-de-mer trade because it occurs throughout Fiji. The other trades are:
LRFF=live reef food fish, AQ=aquarium fish, LR=live rock, and LC=coral.

percent of respondents collected bêche-de-mer. Of these, 71% also engaged in artisanal or subsistence fishing. In villages where bêche-de-mer was harvested, respondents often indicated that most women participated in collecting the invertebrates.

The live reef food fish trade (LRFF) is concentrated in one village on Tavea Island in Bua Province, Vanua Levu, where around 25 fishers participate in the fishery. The aquarium and live rock and coral trades are concentrated along the Coral Coast, and in 3 to 4 villages around Suva and Navua (Fig. 1). In a typical live rock operation along the Coral Coast, around 8 collectors were observed harvesting live rock. However, the number of harvesters varies, and can range from 2 or 3 to 8. Table 2 provides a summary of the spatial distribution of the coral reef trades in Fiji.

Table 2. Summary of spatial distribution of coral reef trades in Fiji.

TRADE	SPATIAL DISTRIBUTION	LOCATION
Bêche-de-mer	Widespread	Coastal villages throughout Viti Levu, Vanua Levu, Kadavu, Yasawa, Lau
Live reef food fish	Limited	1 village in Bua Province, Vanua Levu
Aquarium fish	Limited	Villages along Coral Coast & Lautoka
Live rock	Limited	3 villages along Coral Coast, & 3-4 villages around Suva and Navua*

* Source: Why and Tuwai (2005).

Economic benefits

Thirteen percent of respondents relied on a coral reef export trade for their main source of income, while for the rest it was a supplemental form of income (Table 3). The majority of those who depended on an export trade for their primary source of income were involved in the live reef food fish trade. Bêche-de-mer was the most common provider of supplemental income, and on average accounted for 29% of total fishing income.

Table 3. Level of dependence on coral reef export trades as a source of income

TRADE	INCOME SOURCE	
	Main	Supplemental
Live reef food fish	√	
Bêche-de-mer	√	√
Aquarium fish	√	
Live rock		√
Live coral		√

The net weekly income for collectors of reef resources for each coral reef trade is shown in Figure 2. Collection of aquarium fish generated the highest net weekly income (USD265), while harvesting live coral provided the least income (USD39). However, when compared to the 2002/2003 Fiji National Basic Needs Poverty Line income of USD97 (FJD178) household^{-1}week^{-1} (http://www.fiji.gov.fj/publish/page_5838.shtml), only the aquarium and live rock trades provided sufficient income to meet this baseline.

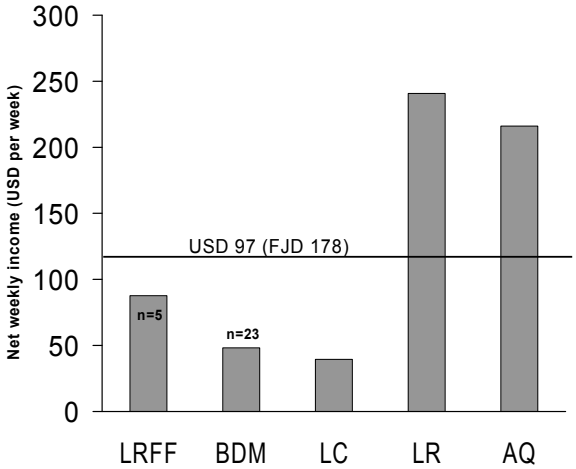

Figure 2: Net weekly income for participants in the coral reef export trades. The line shows the national basic needs poverty line income of USD97 household^{-1}week^{-1}. Results for LRFF (live reef food fish, mean ± standard deviation=USD87±26) and BDM (bêche-de-mer, USD48±11) are derived from fisher interviews, with sample sizes (n) indicated. Results for AQ (aquarium fish, USD 216) are based on an interview with an aquarium fish exporter in Fiji. Data for LC= live coral (USD40) and LR=live rock (USD241) are from Lal and Cerelala (2005).

Discussion

We aimed to quantify the economic benefits of the export trade in coral reef resources to Fijian communities. Our findings indicate that on the whole, the coral reef resources export trade provides economic benefits to coastal villagers in the 8 study sites. We recognise that our small sample size may limit the ability to generalize this study to Fiji as a whole. However, the consistent responses we obtained from interviewees across a wide geographical coverage indicate that our findings are likely applicable throughout Fiji. In any case, this study is useful for providing a preliminary overview and identifying broad patterns of how the trade in coral reef resources affects communities in different parts of Fiji.

The bêche-de-mer trade provides the most widespread benefits, as it occurs near shore and in most cases requires no specialized gear[1], such that almost all members of society are able to participate in it. In fact, Fijians have been involved in the bêche-de-mer trade for over a century to supply the international demand for these invertebrates (Adams 1992).

In contrast, the live reef food fish trade is limited to around 25 participants in one village, and although it provides the primary source of income for these participants, the trade only makes a limited contribution to Fijian communities on the societal level. Similarly, the economic benefits of the aquarium fish and live rock trades are limited to villagers in a specific region of Fiji. The relatively low level of participation in the aquarium and live reef food fish trades can be attributed to the need for special skills. Aquarium fish collectors use SCUBA equipment to collect the target fish species. The equipment, as well as SCUBA training, is provided by the aquarium fish company. Similarly, live reef food fish fishers were trained on how to handle live fish, as fishing for live fish is not a traditional Fijian fishing technique. On the other hand, the collection of live rock and coral is constrained to distinct villages along the Coral Coast due to the presence of fringing reefs along this area.

Our preliminary findings indicate that overall, coral reef export trade is a supplemental, rather than primary, source of income for coastal villagers. In fact, as shown in Figure 2, in most cases, depending on one export trade alone for income is not sufficient to meet minimal household expenditure needs. For example, we observed that women tended to use proceeds from selling bêche-de-mer to pay for day to day household requirements, while big ticket items tended to be purchased and paid off from the domestic sale of fresh fish. This indicates that for participants in the coral reef export trades, it is critical to pursue a diversified livelihood strategy, and, therefore, that the condition of reef resources in coastal areas is important for all fishing community members. Our findings, as well as those of other surveys (e.g., see van Beukering et al. 2007; Veitayaki et al. undated), show that many villagers do in fact adopt a diversified livelihood strategy. For instance, the vast majority (71%) of respondents who collected bêche-de-mer also engaged in other fisheries. Moreover, in addition to participating in the reef export trades, many respondents also engaged in multiple subsistence activities such as planting crops and handicraft making, or finding temporary paid employment.

Engaging in a variety of income-earning activities is consistent with socio-economic studies in other parts of Fiji (Veitayaki et al. undated; Turner et al. 2007), and is an important strategy for ensuring sustainable livelihoods (Allison and Ellis 2001). Having the ability to adapt to another livelihood is particularly important given the ecological concerns connected with the coral reef export trades (e.g., Kolm and Berghund 2003; Sadovy et al. 2003; Rowlands et al. 2005; Why and Tuwai 2005).

The sustainability of bêche-de-mer exploitation in Fiji has been a concern since the 1990s (Adams 1992), as holothurians tend to be susceptible to overfishing (Uthicke and Conand 2005). In at least two villages we visited, villagers no longer collected bêche-de-mer as the invertebrates could not be found anymore. Similarly, adverse ecological impacts have been documented in connection with the collection of live rock and aquarium fish in Fiji (Sykes et al. 2003; Why and Tuwai 2005). Likewise, the live reef food fish trade has led to the collapse of these targeted fisheries in parts of Southeast Asia (Sadovy et al. 2003; Scales et al. 2006). There are indications that the live reef food fish fishery based in Bua Province is experiencing a decline too, as interviewed fishers claim that it is increasingly difficult to catch the targeted grouper species.

When an export market fails, for example through local species extirpation or the departure of a buyer, fishing provides a safety net for villagers. This was the case when a live reef food fish company departed from a village in Vanua Levu, and when the bêche-de-mer fishery collapsed in other villages. As such, protecting the health of marine resources in Fiji is crucial not only to maintain economic benefits from the export trade in coral reef resources, but also, to maintain the survival of coastal communities when that same trade fails.

[1] In some villages, fishers may use SCUBA gear to collect bêche-de-mer species that occur at greater depth.

In conclusion, the coral reef export trade in Fiji can be considered economically beneficial to coastal communities. However, for many participants these trades are mainly a source of supplemental, rather than primary, income. The bêche-de-mer trade provides the most widespread benefits to communities throughout Fiji in terms of being accessible to the greatest number of participants. The live rock and aquarium fish trades provide the highest net income to collectors, but the benefits of these trades are limited to a few villages. The ecological impact of coral reef export trades, together with the fact that it cannot provide a primary source of income, underlines the importance of pursuing a diversified livelihood. At the same time, management policies should be strengthened to ensure the sustainability of inshore fisheries resources, as villagers continue to rely on these marine resources as their safety net when certain coral reef export trades fail.

Abstract. Coral reef fisheries are complex systems. This is due primarily to the multi-species, multi-gear and high labor mobility that often occurs within the fisheries sector. Since many small-scale fisheries operate in remote areas and/ or in developing coastal states, the quality and quantity of data necessary to undertake basic fisheries management, including robust stock assessments, are often lacking. It is becoming more widely acknowledged that local stakeholder participation is an essential pre-requisite to improve overall management of the resource, but this has rarely engaged them directly within a stock assessment framework to provide information on the status of the resource. This study presents a summary and comparison of three pilot studies undertaken in Turks and Caicos Islands, Zanzibar and Puerto Rico. Through the development of a participatory fish stock assessment (ParFish) methodology, fishers are engaged at the beginning of an ongoing adaptive management process to contribute their valuable knowledge about the fishery. Using a Bayesian statistical model, information obtained from fishers help inform prior statistical distributions that are used to estimate parameters in the stock assessment model. The results have shown that this approach can be used successfully to establish preliminary results of stock status in data limited situations.

Key words: Reef fisheries, Data limited, Stakeholder participation, Stock assessment, ParFish

Introduction

The future health and status of coral reefs are threatened from many sources, including environmental and anthropogenic impacts such as climate change, pollution and fisheries (Carpenter et al. 2008). Coral reef fisheries provide a valuable source of income and source of protein for many coastal communities, although the status of reef fisheries has been exacerbated by poor management (Munro 1996).

One important pre-requisite for effective fisheries management is information on the status of the resource. However, in many regions of the world, fisheries data are often lacking due to limited funding and capacity within fisheries management agencies. A lack of quantitative fisheries information has prohibited the use of traditional stock assessment models to assess the status of the stocks, without which sustainable catch control limits cannot be determined. Moreover, without effective monitoring, control and surveillance, illegal, unreported and unregulated fishing is likely to undermine existing management measures.

Fisheries management has now recognized the importance of stakeholder participation, and the potential benefits of co-management initiatives are well documented (Wilson et al. 2004). Until recently, however, fishers and key stakeholders have not been directly involved in the assessment of the stock.

This paper describes the results from three pilot studies that have been used to test a rapid assessment technique that uses fishers' knowledge and information to parameterize traditional stock assessment models without need of a long time-series of data. The results of the Participatory Fish Stock Assessment (ParFish) methodology (Medley 2006) are described in an attempt to determine if it can be used successfully in the field.

Material and Methods

The ParFish methodology was developed under the Fisheries Management Science Programme (FMSP) (www.fmsp.co.uk) funded by the UK Department for International Development (DFID). It is an adaptive process that includes six key stages to (i) understand the context of the fishery (ii) agree objectives of the study with stakeholders (iii) undertake the ParFish

stock assessment (iv) give feedback of the results and initiate management planning (v) assist with the implementation of the management plans, and (vi) evaluate the ParFish process.

The ParFish approach is supported by two main components: a toolkit that provides guidance on the process outlined above and the ParFish software. The software enables the analysis of the data, based on Bayesian statistics and decision analysis. Quantitative data used to develop statistical probability distributions (or priors) of parameters used in the stock assessment are obtained from interviews with fishers. In addition, preference interviews are used to score individual fishers' utility (i.e. risk seeking or risk averse) to selecting different management options based on changes in fishing effort (cost) and expected catch (benefit). A full description of the ParFish methodology and toolkit can be found in Walmsley et al. (2005).

Development of ParFish is ongoing, and this study presents a summary of the results obtained from pilot studies occurring within the Caribbean region (Turks and Caicos Islands and Puerto Rico) and Africa (Zanzibar Island, United Rep. Tanzania).

Turks and Caicos Islands

A pilot study funded by DFID was conducted to assess the status of the queen conch (*Strombus gigas*) on the islands of Provenciales and South Caicos (Fig. 1). This fishery provided a useful test for the value of the fisher interviews since a long time series of catch and effort data is available for comparison.

The fishery is targeted by small day boats with fishers who free dive to 10m depth to collect conch that is shelled at sea. The meat is landed and recorded at processing plants. These data, available since 1974, are used to record catch and effort information and have subsequently been used to estimate stock size from a logistic biomass model (Medley and Ninnes 1999). The data collected from processing plants are used by the government to set catch quotas for landings and exports (Taylor and Medley 2003a).

With the assistance of the Department of Environment and Coastal Resources (DECR), a total of 46 stock assessment and 38 fisher preference interviews were conducted between 3rd and 21st July, 2003.

In addition to the comparison between the stock assessment and the ParFish results, a simple retrospective analysis was performed to see if the interviews alone might have improved the management of the fishery, had that information been used to set effort control back in 1974.

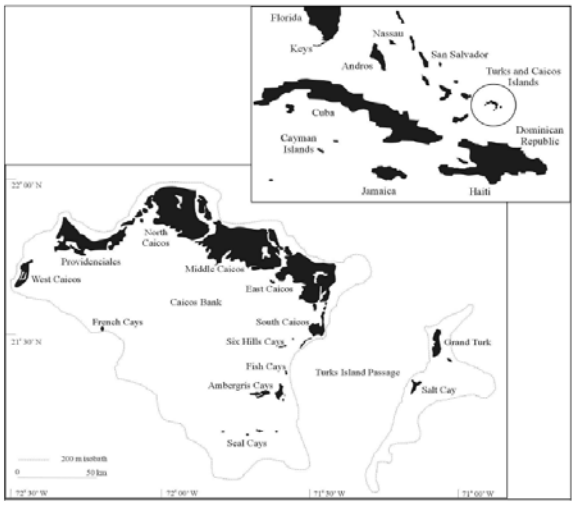

Figure 1: Location of ParFish assessment in Provenciales and South Caicos within Turks and Caicos Islands during ParFish assessment.

Zanzibar

A pilot study funded by DFID was conducted to assess the status of a multi-species fishery on both the offshore patch reefs (Dimbani) and inshore fringing reefs (Mkunguni and Mtende) in the Kizimkazi region of southern Zanzibar (Fig. 2). The field sites also fall within the boundaries of the Menai Bay Conservation Area which was listed as a multiple-use management area in 1997 (ref here). To date, no restrictions are placed on the minimum size of capture or catch limits.

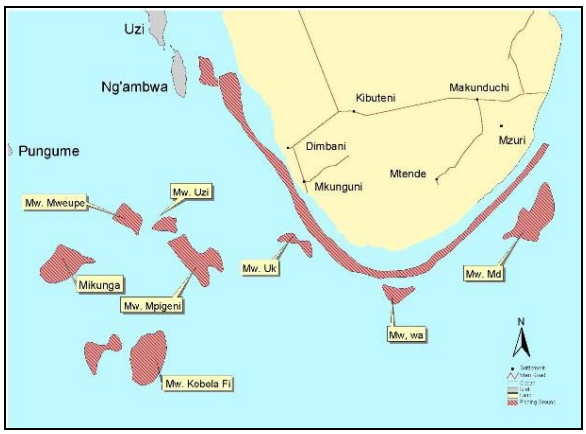

Figure 2: Location of ParFish assessment in Kizimkazi, southern Zanzibar Island during ParFish assessment.

The fishery provided a further opportunity to develop the ParFish interview technique and develop the participatory process but also included a range of auxiliary information from research experiments. This included fishing experiments, underwater visual census (UVC) and mark and recapture of fish within the experimental area (Taylor and Medley 2003b).

With the collaboration of the Institute of Marine Science, University of Dar es Salaam, a total of 92

stock assessment and 67 preference interviews were completed between April and June, 2003.

Fishing Experiments

Depletion techniques reduce the population size through fishing to provide parameters necessary to estimate stock size (Hilborn and Walters, 1992). An important assumption of depletion methods is that no immigration or emigration occurs in the population during the experiment, and thus would preferably be conducted over a short time period. In Dimbani (offshore reef), the fishing experiment was conducted over an area of 600 x 500m during an eight day period with approximately 55 fishers while in Mkunguni and Mtende (inshore reef), this was conducted within an area of 800 x 100m with an average of 43 fishers during a nine day period. Log books were provided to all fishermen to record fishing duration and catch by species.

Underwater Visual Census (UVC)

A UVC, using similar methods to Gaudian et al. (1995), was conducted at Mkunguni and Mtende (inshore reef sites). Six permanent monitoring stations were established in the study area: two within the fishing area for the depletion experiment and two on either side of the experiment area. Each transect (200 x 10m belt) was conducted by two pairs of divers, each recording the target species within the transect boundaries. These sites were monitored at random (as far as possible) before, during, immediately after, and one month after the fishing experiment.

Mark and Recapture Studies

The use of mark and recapture techniques in the ParFish experimental design was investigated at Mkunguni and Mtende (inshore reef sites). Following the demarcation of the fishing experiment, an intensive tagging program was conducted during eight days within the same area. During the tagging phase 566 fish from 35 different species were marked and released within the boundaries of the fishing area. The depletion experiment was then used to recapture the tagged fish, in addition to recording tagged fish during the UVC.

Puerto Rico

A pilot study funded by the NOAA Cooperative Research Program was conducted to assess the status of the two most important deepwater snapper: queen snapper (*Etelis oculatus*) and silk snapper (*Lutjanus vivanus*) in western Puerto Rico. The study enabled the ParFish software to be further developed to include a yield-per-recruit analysis in addition to the existing logistic production model.

Deepwater snapper are targeted by a small-scale hand line fishery using electric reels and multiple baited hooks. Approximately 30 to 40 full-time commercial fishers operate from two main fishing centers, Rincón and Cabo Rojo. Standardized catch and effort data are available through SEAMAP surveys (Rosario Jimenez 1989), although these have been shown to be of limited use for the assessment of the snapper complex (Ault and Rothchild 1991). To date, management of the fishery employs a closed season for silk snapper and minimum size limits for both species. There are no catch limits placed on either species.

With the assistance of the Department of Natural Resources and the Environment, a total of 31 stock assessment and 29 preference interviews were conducted between March and June 2008.

Results

Turks and Caicos Islands

The results of the ParFish stock assessment are associated with high uncertainty in the status of the conch stock, although overall there is a greater tendency to indicate the stock is overfished. The scientific data from the catch and effort time series supports the fishers' view that the fishery is in an overfished state. When interview and scientific data are combined the posterior opinion is that the fishery is overfished (Fig. 3).

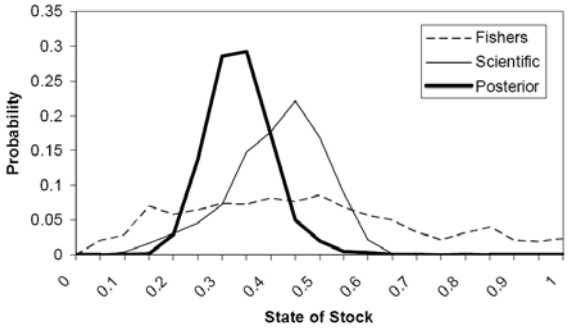

Figure 3: State of stock (current biomass / initial biomass) estimated from ParFish interviews, scientific catch and effort time series data and combined analysis (posterior distribution).

Similarly, the ParFish assessment showed high uncertainty in the level of fishing effort although overall there was a higher probability that overfishing was occurring, or at the very least fishing at the maximum (status greater than 1). Again, the scientific data supports the fishers' view that the stock is overfished. When interview and scientific data are combined, the posterior opinion shows that the stock is either currently overfished or very close to being in an overfished state (Fig. 4).

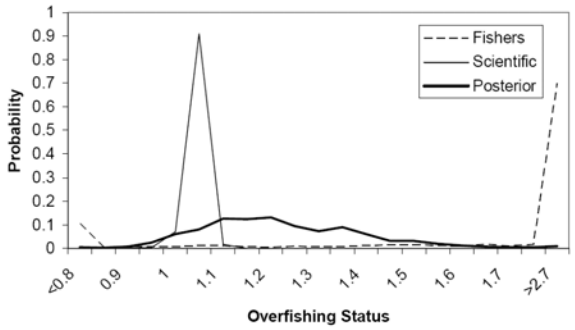

Figure 4: Overfishing status of stock (current fishing mortality / fishing mortality at MSY) estimated from ParFish interviews, scientific catch and effort time series and combined analysis (posterior distribution).

Since the fishery is managed on a catch quota system, the results from the ParFish stock assessment and preference interviews were used as part of a retrospective analysis (Fig. 5) to evaluate the impacts if an appropriate catch level had been applied back in 1974.

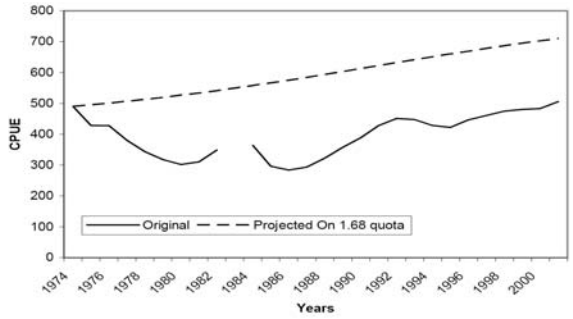

Figure 5: Expected catch per boat day (CPUE) from the fitted logistic model (original) and the projected CPUE from the annual catch quota (1.68 m pound) estimated from ParFish interviews.

Assuming the logistical model can represent the dynamics of the fishery, the results show that the total catches over the period 1975-2002 were very similar (approx. 46 million pounds; not shown). There was, however, a marked increase in the catch rate. This suggests that far less effort (and costs) would have had to be exerted than is now applied (from 3,300 boat days down to 2,500 boat days).

Zanzibar

The results of the ParFish assessment indicate that the current states of both the offshore and fringing reef multi-species fisheries are unknown, although the balance of probabilities suggests that the offshore fishery is overexploited. The results from the interviews suggest that too little is known about the initial state of the stock, which has been exploited for generations and is likely to provide unreliable estimates of unexploited biomass. In addition, there is no evidence to indicate overfishing is occurring in either fishery, although further increases in fishing effort should be capped until more information on the state of the stock can be determined.

The results of the fishing experiments showed that fishers were able to deplete the population on a local scale for both offshore and fringing reef populations sufficiently to estimate initial biomass that could be used in the ParFish assessment (Fig. 6).

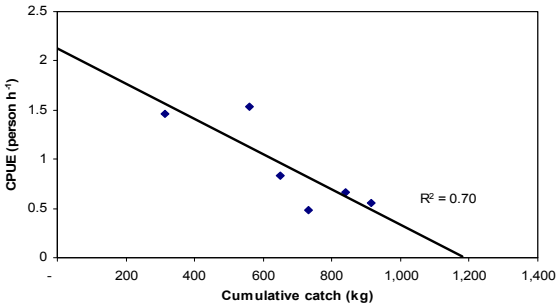

Figure 6: CPUE against cumulative catch to show depletion of population on a local scale for fringing reef fishery. Data represents days 4 -9 of the experiment.

The results of the UVC demonstrated that the abundance of the selected target species was reduced by the fishing experiment (Fig. 7). The increase in number of fish reported one month after the experiment indicates the population may experience immigration on a small scale.

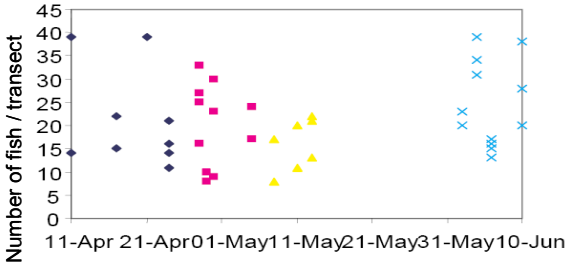

Figure 7: Density of fish observed at monitoring station on fringing reef, before (diamonds), during (squares), immediately after (triangles) and 1 month after (crosses) the fishing experiment.

During the fishing experiment, 56 tagged fish were recovered and provided a fishery-independent estimate of population size for the fishery. The mark and recapture data could also be used for estimating the population sizes of individual species for inclusion in multi-species assessments.

Puerto Rico

The assessment is still in process and the results show a high uncertainty associated with the parameters but that the probability of the current level of biomass for queen snapper being below the MSY level is slightly higher than 50% (i.e. possible overfished). In addition, the current yield from the analysis suggests that overfishing is not occurring.

Discussion

The results of the pilot studies have demonstrated that the ParFish methodology can be used to collect quantitative information from small-scale fisheries sufficient to parameterize traditional stock assessment models such as the logistical production and yield-per-recruit models using a Bayesian statistical framework. The methodology provides a rapid assessment of the stock, which does not require a long time-series of catch and effort data.

The robustness of the assessment results can depend on the quality and quantity of interview data obtained. It is therefore important to develop a good rapport with fishers and key stakeholders at the beginning of the study. This may require considerable outreach, but can help manage expectations and indicate the likely benefits of the results. Furthermore, it can lead to more effective involvement of fishers in the management process and development of regulations.

In comparison with more formal stock assessments, the initial ParFish results can exhibit high levels of uncertainty. This is to be expected however, given the diverse array of opinions and level of fisher experience. Options to help reduce the overall level of uncertainty in the results may include (i) ensuring that all fishers fully understand the questions being asked (ii) re-interviewing fishers with different questions that lead to the same answer, and (iii) asking very specific questions about a fixed attribute (e.g., closed area/ season etc.) that can be compared among fishers to measure sampling variability.

ParFish should not be viewed as a single one-off assessment, but part of an ongoing participatory adaptive learning and management process. To further help reduce the level of uncertainty in the results, information gathered from fisher preference interviews can be used to establish a consensus of opinion with management agencies to develop alternative levels of fishing effort. For example, fishers in Zanzibar have recognized that a reduction in fishing effort can be implemented by better enforcement of existing regulations to prevent illegal fishers from entering the fishery. Within a ParFish full assessment, these would become re-evaluated with new research and data collection programs to ensure catch rates can be improved by lowering fishing effort.

In conclusion, the ParFish methodology may be used where little or no previous data are available to conduct more formal stock assessments. It can be a useful tool in helping to establish initial catch limits and develop management options in collaboration with the fishers. A full ParFish assessment would include ongoing adaptive learning and management to further improve catch rates within the fishery and reduce the level of uncertainty in the results.

Acknowledgement

ParFish was originally developed under the Fisheries Science Management Programme funded by the UK Department for International Development (DFID) and further developed under the NOAA-funded Cooperative Research Programe. A number of people and institutions were instrumental in its development, in particular, Dr Narriman Jiddawi, Dr Omar Amir and Saleh Yahya, Institute of Marine Sciences, Zanzibar; Charlotte Tindall, MRAG; Oliver Taylor, Five Oceans Environmental Services LLC; Nancie Cummings, SEFSC, Miami; Eugenio Piñeiro, CFMC. We would also like to thank all the fishers who were involved in the ParFish interviews.

Abstract. Papua New Guinea supports some of the most healthy and biologically diverse coral reefs. Coastal communities have customary tenure over fringing reefs and inshore fishing resources. Closure of an area of reef to harvesting (*tambu*) has historically been employed as a form of customary management. This study investigates the short-term response to this kind of management of moderately exploited coral reef fish communities. Fish biomass and abundance were surveyed by underwater visual census at three managed sites immediately before closure and at three nearby fished control sites at the 4m and 7m depth contours. This survey was repeated one year after closure. Our results display a significant increase in overall biomass within managed areas compared to control sites. We recorded significant increases in biomass and density of piscivorous fish at shallow transects in the managed areas, whilst piscivore biomass significantly decreased within shallow transects at control sites. Overall density of the fish communities remained largely unchanged. Serranids and Lutjanids showed the greatest change in biomass and density in managed areas. These short term positive results can be used to encourage communities to restore customary resource management.

Key words: Customary management, reef fish, Papua New Guinea, marine protected areas, no-take zones

Introduction

It is now well established on a variety of scales and in different regions of the world that marine protected areas (MPAs), in particular well enforced no take zones (NTZs) are effective at promoting recovery of reef fish populations (McClanahan 1994, McClanahan and Kaunda–Arara 1996, Halpern and Warner 2002, Russ et al. 2005). There remains some debate over the mechanisms and speed of recovery of a fish community from high fishing pressure (Halpern and Warner 2002, Russ et al. 2005). Often there is a large initial response to protection from harvesting (Halpern and Warner 2002), however studies in Kenya and the Philippines have indicated that the trajectory of recovery slows and full recovery from fishing may require more than a decade to occur (Russ and Alcala 2003, McClanahan and Graham 2005).

In Melanesia systems of customary marine tenure, heavy reliance on marine resources and heterogeneous perceptions of the status of marine resources (Cinner et al. 2005, Turner et al. 2007) have resulted in the failure of large-scale MPAs through top-down governmental processes as a conservation tool (McClanahan et al. 2006). In Papua New Guinea (PNG) historical and cultural factors have combined to form a regime of customary marine tenure that operates at the family, clan and village levels. This tenure and rights over the fishing resources within the tenure is legally recognised in PNG and provides a potentially useful tool in establishing small scale NTZs to protect reefs, provide refugia for fishery species and promote community involvement in conservation.

This study is part of ongoing research and monitoring of customary no harvesting (*tambu*) areas within the tenure of villages that are dependent on fishing. The work has been conducted by the Wildlife Conservation Society - Papua New Guinea Marine Program (WCS) in New Ireland Province in the Bismarck Archipelago (Fig 1.) Previous studies in the region have focused on spatial comparisons of *tambu* areas and other areas under management or open to fishing; this study is unique in the area, providing a temporal investigation into the effects of small-scale community managed areas in PNG.

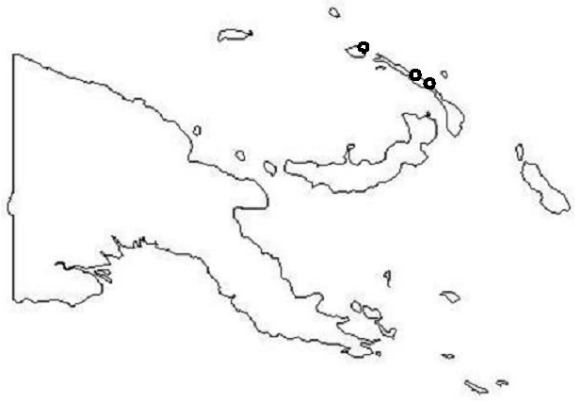

Figure 1. The three survey locations in New Ireland Province, PNG

Methods

Three subsistence fishing communities were identified within New Ireland Province, PNG by WCS in 2006 (Fig. 1). One (Ungakum) is situated in the Tsoi Islands approximately 35km Northwest of the provincial capital Kavieng, and the other two (Lasigi and Silom) are situated between 160 and 200km Southeast of Kavieng in central New Ireland. Criteria for selection of communities were that they were receptive to the reintroduction of customary fisheries management strategies, able to drive the process in partnership with WCS and were close to comparable communities that could be used as control areas. Each area (*tambus* and controls) stretches for between one and one and a half kilometres of fringing reef, and from the shoreline to the bottom of the reef slope or the 30m depth contour.

Through underwater visual census (UVC) the abundances of all non-cryptic, diurnal species of reef fishes >3cm total length (TL) were recorded along two 50m transects at the 4m and 7m depth contours at six sites within each area. At each transect two passes were made, the first recording large fishes (>10cm TL) 2.5m either side of the transect tape, the second recording small fishes (≤10cm TL) 1m either side of the transect tape. All individuals were placed within the appropriate 5cm size class (i.e. 3-5cm, 6-10cm, 11-15cm etc.). This survey method was employed across three customary managed no-take reserves, initially during September/October 2006 (prior to closure to harvesting) followed by a repeat survey twelve months later. Each managed area of reef was paired with a control (fished) area selected on the grounds of being ecologically and geomorphologically similar and situated between 1 and 5km from the managed site. These control sites were surveyed immediately after each adjacent managed area in both 2006 and 2007.

Biomass estimates were obtained using length-weight conversion factors obtained from Fishbase (Froese and Pauly 2006). Length data used in biomass calculations used the midpoint of size classes. Before any parametric statistical test, data met all assumptions for normality.

Results

After 12 months of closure our results showed six major trends:

1. After one year of closure at the managed areas we recorded a highly significant increase in overall mean fish biomass (one way ANOVA P=0.001) (Fig. 2a) compared with no significant change at the fished control areas (P= 0.537).
2. Overall fish community density showed no significant change in managed areas or corresponding control areas over the same time period (Fig. 2 b).

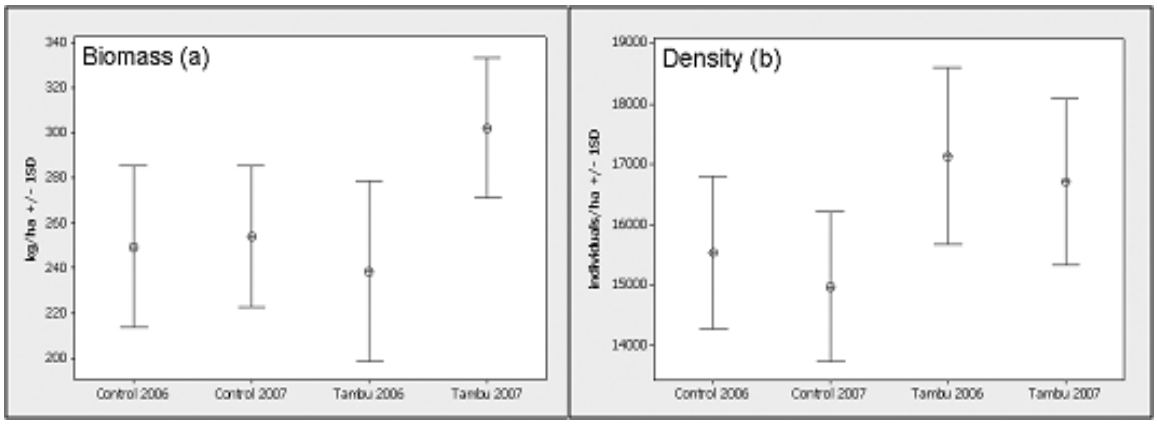

Figure 2. Overall coral reef fish community biomass (kg/ha ±1SD) (a) and density (individual fish/ha ±1SD) (b) at customary managed areas (*tambu*) (2006 and 2007), compared with the three control areas (2006 and 2007).

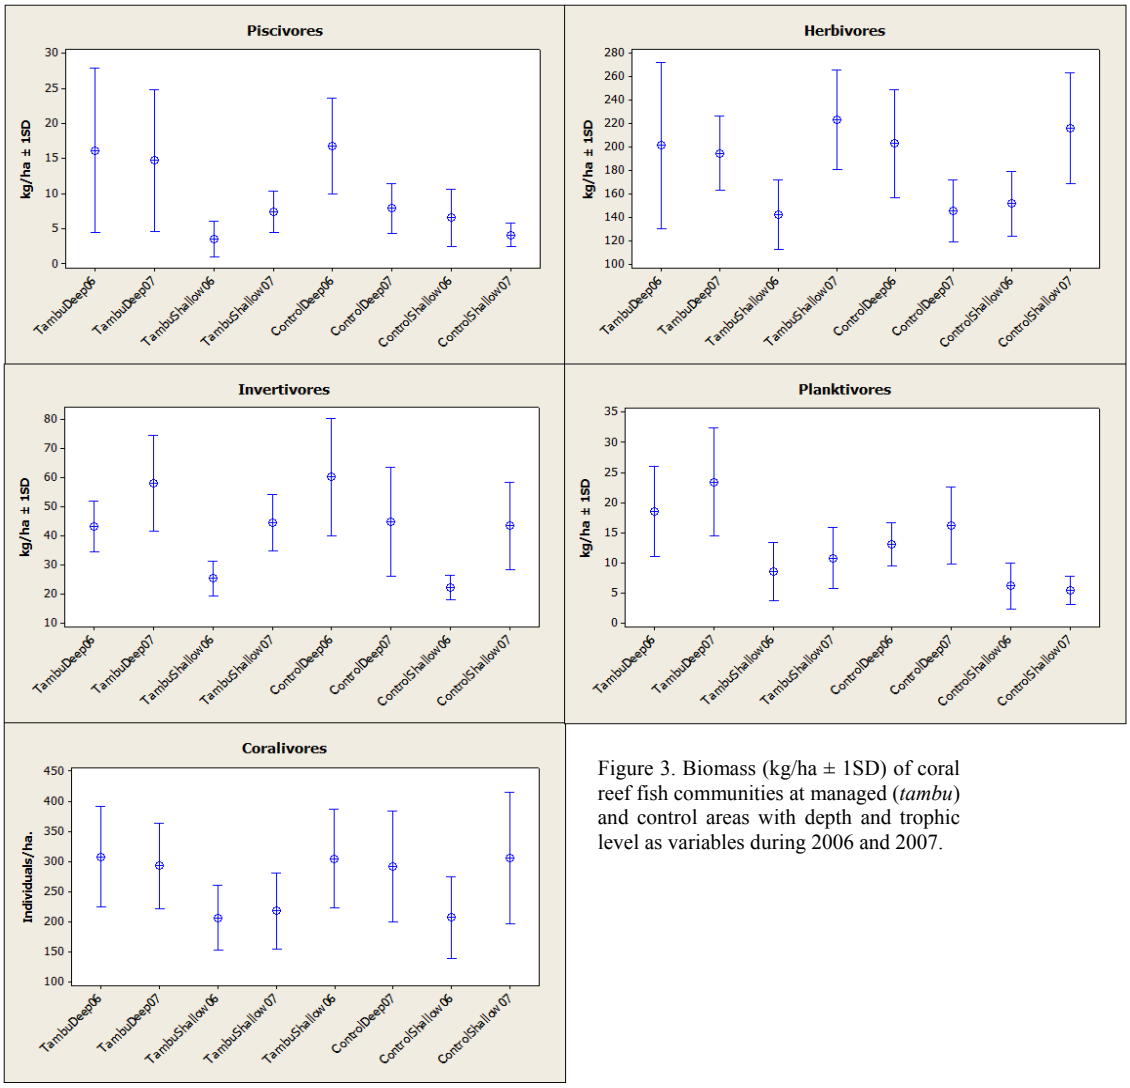

Figure 3. Biomass (kg/ha ± 1SD) of coral reef fish communities at managed (*tambu*) and control areas with depth and trophic level as variables during 2006 and 2007.

Table 1. *P* values (one way ANOVA) of coral reef fish community biomass (kg/ha) displayed in Figure 3 (2006 vs 2007), at trophic level for shallow and deep sites. All assumptions of normality were met for data.

	Tambu	***Control***	***Tambu***	***Control***	***Tambu***	***Control***	***Tambu***	***Control***	***Tambu***	***Control***
	Piscivores		***Herbivores***		***Invertivores***		***Planktivores***		***Coralivores***	
Deep	0.693	0.284	0.220	0.026	0.118	0.061	0.993	0.871	0.090	0.952
Shallow	<0.000	0.228	0.003	0.019	<0.000	0.001	0.414	0.887	0.001	0.007

3 The greatest change in biomass occurred within piscivores at shallow sites. We recorded a highly significant mean increase of 3.83 kg/ha at the managed shallow sites (P<0.000), compared to a non-significant mean decrease of 2.43 kg/ha recorded at the shallow control sites (Fig 3, Table 1). Other changes in biomass were evident across the trophic structure of the fish community, including significant increases in invertivore biomass at both *tambu* and control areas, however none displayed such a large variation between the managed areas and control areas (Fig. 3).

4 There was very little change in the density of the fish population at the trophic level, with the exception of a highly significant mean increase of 115.5 individuals/ha of piscivores (P=<0.000) (Fig. 4, Table 2) at the shallow managed sites.

5 There was a 91.33% dissimilarity between the piscivore community biomass structure at the shallow managed sites between 2006 and 2007 (SIMPER; Table 3).

Table 2. Resulting *P* values (one way ANOVA) of coral reef fish community density (individuals/ha) displayed in Figure 4 (2006 vs 2007), at trophic level for shallow and deep sites. All assumptions of normality were met for data.

	Tambu	*Control*	*Tambu*	*Control*	*Tambu*	*Control*	*Tambu*	*Control*	*Tambu*	*Control*
	Piscivores		*Herbivores*		*Invertivores*		*Planktivores*		*Coralivores*	
Deep	0.061	0.334	0.608	0.179	0.547	0.125	0.532	0.433	0.774	0.834
Shallow	<0.000	0.101	0.091	0.350	0.446	0.123	0.620	0.459	0.777	0.124

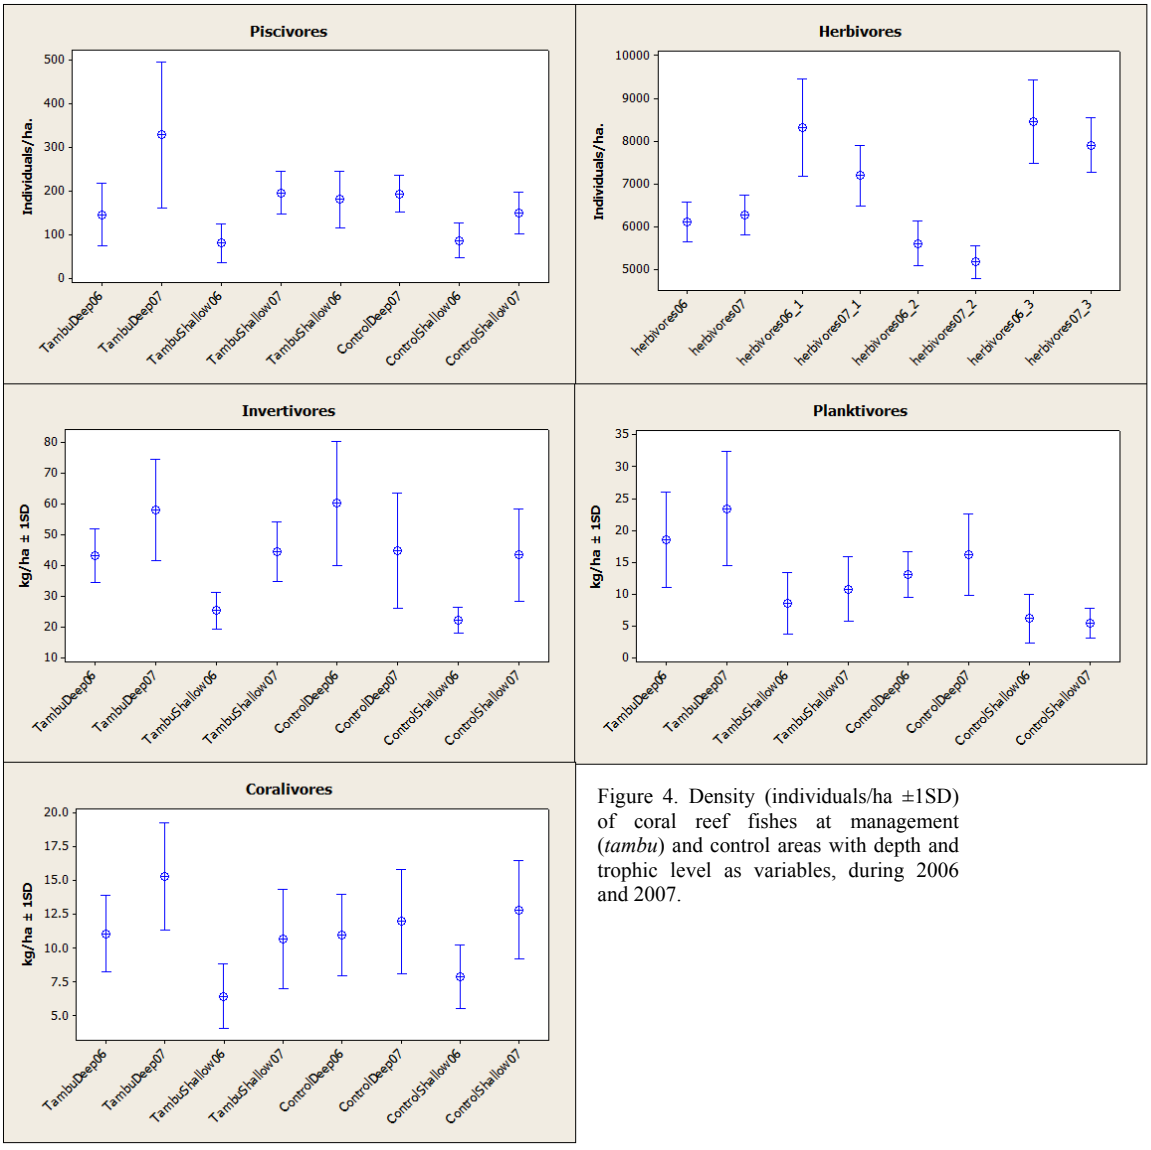

Figure 4. Density (individuals/ha ±1SD) of coral reef fishes at management (*tambu*) and control areas with depth and trophic level as variables, during 2006 and 2007.

6 Serranidae and Lutjanidae contributed 45.01% and 41.46% respectively of the dissimilarity in biomass, with very similar results for fish density (SIMPER; Table 3).

Discussion

Our results support the claims that the biological responses as a result of implementing NTZs appear to develop quickly in some cases. Indeed, Halpern and Warner (2002) state this is often the case and in their review show that NTZs can support higher than average values of density, biomass, average organism size and diversity inside reserves (relative to controls) within a short (1–3yr) time period. Our results are comparable with results from the Great Barrier Reef collated by Evans *et al.* (2006). This study showed

Table 3. SIMPER output of data for biomass of piscivorous families at the shallow managed sites showing change in the percent make up of the community structure between closure (2006) and after one year of closure (2007).

that after just 21 months of closure to fishing, the density and biomass of coral trout (*Plectropomus* spp., family Serranidae), and the lutjanid *Lutjanus carponotatus* had increased by up to a factor of 1.7 in areas that had been closed to fishing, while density and biomass decreased slightly over the same period in the areas that remained open to fishing. If organisms respond quickly to protection, initial rates of change should be greater than later rates. For the seven studies of reserves reviewed by Evans *et al.* (2006) that recorded temporal data, the rate of change for density, calculated as the ratio of the values at one time step divided by the value at the previous time step, was significantly greater for the first time step compared to all other time steps. Our recorded rapid increase in density and biomass at the shallower depths, compared with deeper sites could be attributed to relief from greater fishing pressure at these shallower depths. The most commonly used gears in the region are spear guns and hand lines, making shallow reefs more accessible to fishers. Overall, our results show a rapid, demonstrable, positive response of the targeted fish community to protection. This is a key element in maintaining support for community managed MPAs, particularly NTZs in rural subsistence fishing communities which have governance over their resources.

Abstract. In June 2005, following extensive community consultation, national legislation was enacted to change the boundaries of zones that regulate fishing and other resource use in Karimunjawa Marine National Park in the Java Sea, Indonesia. The new park boundaries included five management zones ranging from no-take areas to open access. An initial increase in fish biomass in 2005 was not sustained and by 2007 there was no significant difference in mean biomass when compared to the initial surveys in 2004. Analysis by trophic groups suggested that the re-zoning was effective in protecting the biomass of many fishes. Indeed, only herbivorous fish biomass declined significantly within the park boundaries between 2004 and 2007; corallivore, omnivore and planktivore biomass increased while invertivore and planktivore biomass remained stable. However, similar patterns were evident outside the park boundaries, suggests other factors may be responsible for these patterns, such as a decline in effort throughout the region, perhaps as a consequences of a reduction in the number of people in the fishery. Some zones were more effective than others at protecting fish biomass. For example, increases in every trophic group, except herbivores, were recorded in the Core Zone and Tourism Zone. In contrast, most groups declined in the Protection Zone, perhaps as a result of a shift of fishing effort. Work in the park is continuing in an effort to identify the cause of these trends.

Keywords: Coral reef, Karimunjawa, management, marine protected area, , monitoring

Introduction

Between the years 2003-2004 the Wildlife Conservation Society (WCS) Marine Program Indonesia assessed the ecological condition of coral reef habitats, and evaluated socio-economic factors that constrain fisheries and conservation management in Karimunjawa National Park (KNP) in the Java Sea, Indonesia (Campbell 2006). In June 2005, following extensive community consultation, and using the data collected above, national legislation was enacted that changed the boundaries of zones to regulate fishing and the use of other marine resources in KNP. The park included five management zones ranging from no-take areas to open access. There were three Core Zones designated as no-take areas to protect three distinct reef habitats identified in the baseline surveys, 7 Protected Zones with limited access to resources, 7 Tourism Zones as no-take areas which nonetheless allowed for marine tourism, three Rehabilitation Zones (designed to allow degraded reefs identified in the baseline survey to recover and four Aquaculture Zones (for sea-weed farming, fish culture, etc.). The remaining areas within KNP were zoned Traditional Fisheries Utilization area (Utilization Zone) where fishing activity was unregulated.

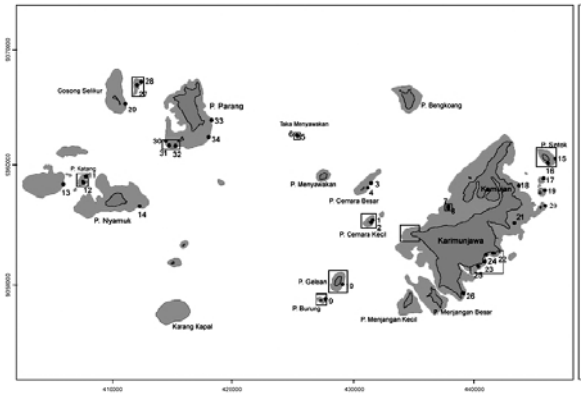

Figure 1. Map of Karimunjawa National Park and 43 survey sites within 5 management regimes.

As part of the ongoing evaluation of the new zoning scheme and as part of the adaptive management of KNP, monitoring has continued in the park. In total 43 survey sites were monitored during the transition time between the west and the east monsoon (April-May) in 2005, 2006 and 2007; The 2003-2004 baseline data (Ardiwijaya et al. 2007). plus surveys from areas outside of the KNP, which are open access, are included for comparison.

Materials and Methods

Fish abundance and biomass were collected using visual surveys at two depths (1 and 7 m) using two replicate 50m transects. A 5m width was used for fish whose Total length (TL) > 10cm and 2m for fish with TL $\leq$ 10cm. Fish TLs were classified into 9 size classes (see Fig. 3). Fish were identified to species following, Myers (1999) and Allen and Steene (1999). Fish data were analyzed using two-way ANOVA to test for significant differences between years and management regimes.

Fish from the family Pomacentridae (damselfish) were eliminated from the analyses to enhance precision since they are found in high and highly variable abundance within all survey sites. In 2005, there was no data collected outside the KNP. Consequently, the mean of sites of all other years was used as a baseline in ANOVA. All abundance and biomass values were $\log_{10}$ transformed.

Results

Mean fish abundance in the KNP fluctuated considerably among years and was significantly higher at the last census in 2007 when compared to 2004 (Fig.2a). In contrast, there was no significant increase in fish abundance outside KNP (Fig. 2a). Fluctuations in fish abundance in the KNP were driven mostly by changes in the Core Zone where a 100% increase in fish abundance occurred between 2004 and 2007 (Fig. 2a). Fish abundance did not vary significantly among years in any of the other zones (Fig. 2a). In contrast to abundance, fish biomass in KMP did not change between 2004 and 2007. An initial 20% increase in fish biomass in KNP in 2005 was not sustained. A significant increase in fish biomass in the Core Zone was counteracted by a significant decrease in the Protected Zone (Fig. 2b).

In general, an increase in abundance accompanied by decrease in biomass would suggest more small fish and/or less large fish. Yearly graphs of fish abundance in 9 size classes shows an increase in small (<10cm) and large fish (> 40cm) that was more than compensated for by an decrease in all size classes between 20 and 40cm (Fig. 3).

Benthic invertivore biomass was dependent on survey period and management zone (interaction term $F_{12,134}$=2.557; P=0.004). In the KMP as a whole there was no change in biomass of invertivores because significant increases in the Core and Tourism zones were counteracted by decreases elsewhere. (Fig. 4a).

Carnivorous fish biomass was dependent on survey period and management zone (interaction term $F_{12,134}$=2.267; P=0.012).

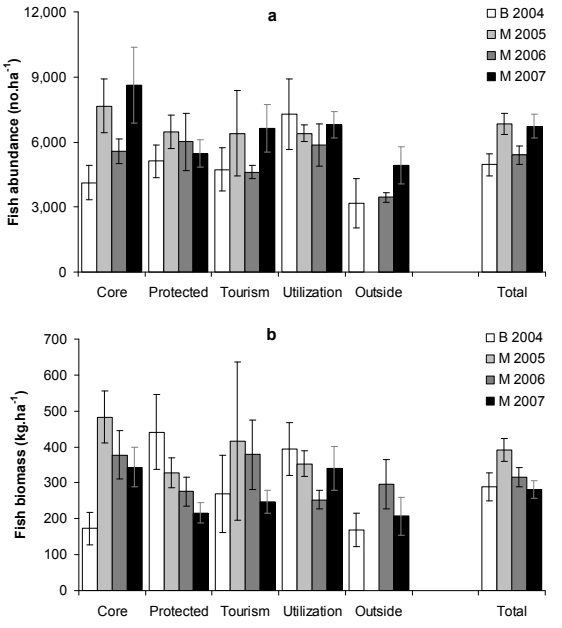

Figure 2. Mean (±SE) (a) abundance (no.ha^{-1}) and (b) biomass (no.ha^{-1}) of reef fish (excluding family Pomacentridae): comparison between management zones and survey periods.

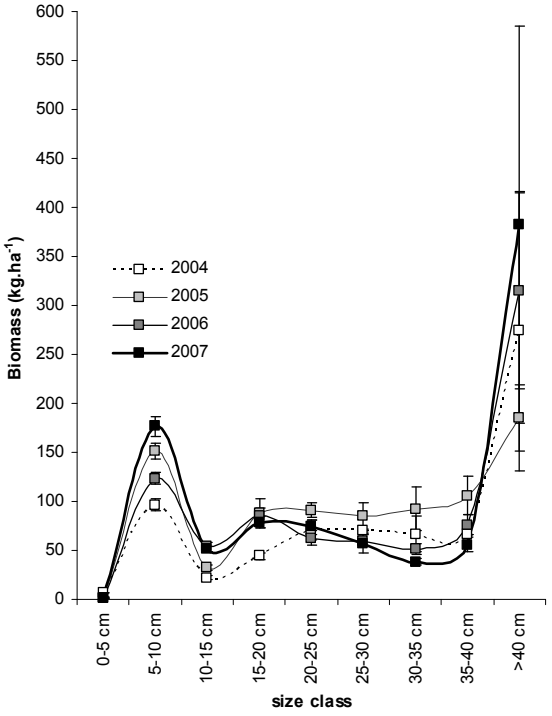

Figure 3. Mean (±SE) biomass (kg.ha^{-1}) of reef fish (Family Pomacentridae excluded): comparison between size classes.

In the KMP as a whole there was no change in biomass of carnivores because significant increases in the Core and Tourism zones were counteracted by decreases elsewhere (Fig. 4b). Similarly, the biomass

of carnivores outside the KNP in 2007 was not significantly different to that in 2004 (Fig. 2b).

Corallivorous fish biomass was dependent on survey period and management zone ($F_{12,134}$=1.886; P=0.044). In the KNP as a whole, biomass increased between 2004 and 2007 by nearly 100% driven mostly by large increase in the Core and Tourism Zone (Fig. 4c). A similar increase was apparent outside the KNP (Fig. 4c).

Herbivorous fish biomass was dependent on survey period and management zone ($F_{12,134}$=2.616; P=0.004). Large increases in the biomass of herbivores in the Core and Tourism Zones between 2004 and 2005 where not sustained and were more than compensated for by a large decrease in biomass in the Protected Zone between 2004 and 2007. The result was a 20% decline in herbivore biomass in KNP between 2004 and 2007 (Fig. 4d). Further analyses of the grazing parrotfish family Scaridae where performed to see how this family contributed to the patterns in biomass of herbivores. The patterns in biomass of the scarids among zones and years are very similar to those of the trophic group as a whole suggesting fluctuations in the abundance of this family is driving the patterns in the group (Fig. 5).

Omnivorous fish biomass was dependent on survey period and management zone ($F_{3,134}$=15.047; P<0.05). In the KNP as a whole, biomass increased between 2004 and 2007 by nearly 100%, driven mostly by large increases in the Core and Protected Zones (Fig. 4e). A similar, but not significant, increase was apparent outside the KNP (Fig. 4e).

Planktivorous fish biomass was dependent on survey period and management zone ($F_{3,134}$=9.562; P<0.05) In the KNP as a whole, biomass increased between 2004 and 2007 by nearly 200% driven mostly by large increases in the Core and Tourism Zones (Fig. 4f).

The omnivore trophic group was dominated by the family Pomacentridae which made up 70% of total abundance and 26% of biomass from all families. The planktivore trophic group was dominated by the family Caesionidae which made up 20% of total biomass (Fig. 6).

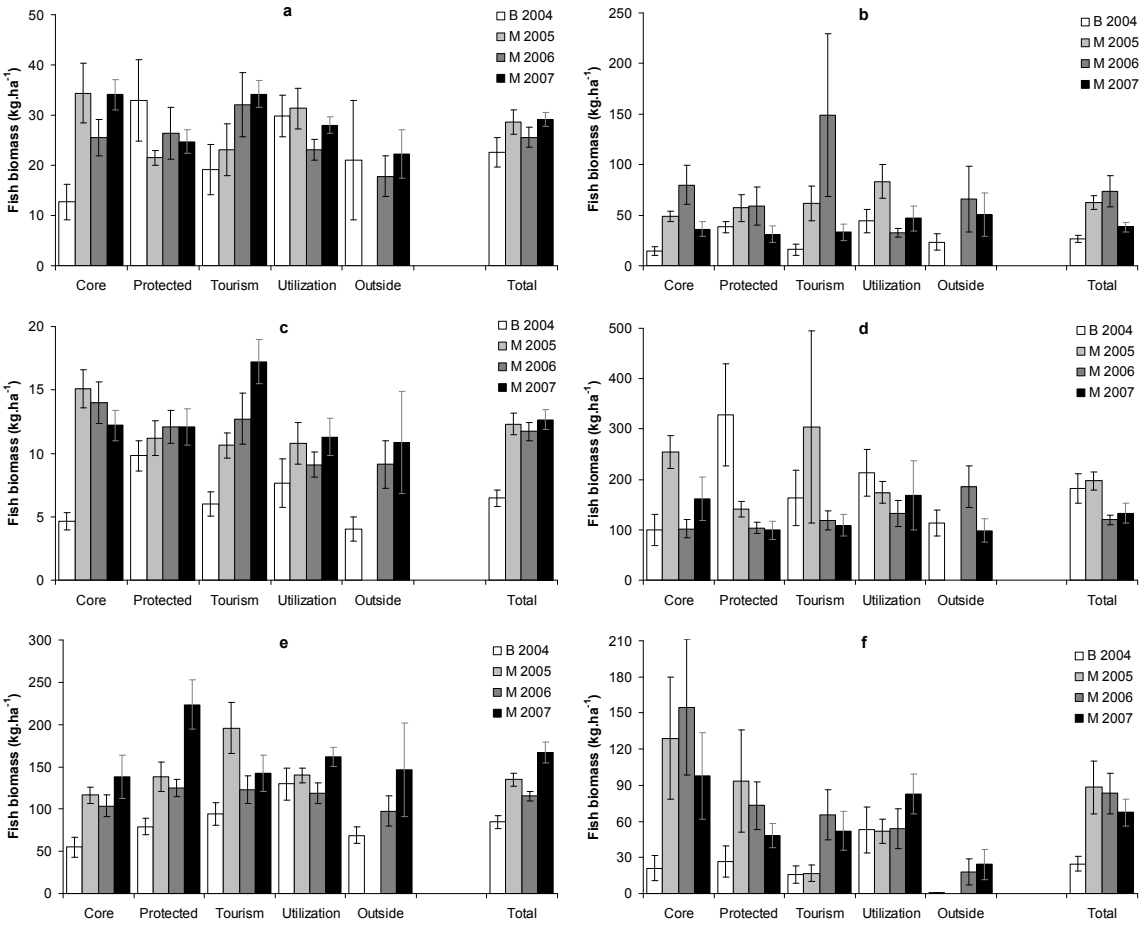

Figure 4. Mean (±SE) biomass (kg.ha^{-1}) of (a) benthic invertivore, (b) carnivore, (c) corallivore, (d) herbivore, (e) omnivore, and (f) planktivore: comparison between management zones and survey periods.

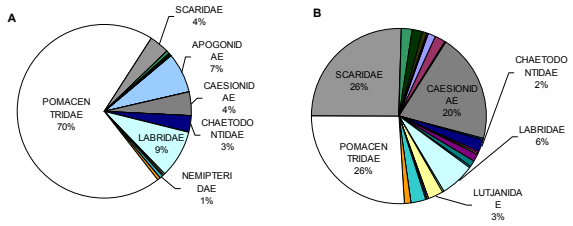

Figure 6. Composition of fish family by abundance (A) and biomass (B).

Discussion

Several interesting trends are apparent in these data. Slight increases in fish abundance has not delivered an increase in biomass, because the size structure of the assemblage now includes fewer fish in the size range from 20cm to 40cm. However, a number of trophic groups have increased in biomass since the re-zoning. In particular, the biomass of corallivores, omnivores and planktivores has all increased since the re-zoning in 2005. While these increases may not be of interest to fishermen, because few of these fish are targeted, they are potentially good news for the tourist industry. The corallivorous family, Chaetodontidae, are of particular interest to recreational divers. The biomass of invertivores and carnivores, the main target species for fisherman, remained stable within the KNP. Consequently, the re-zoning has been a partial success for these groups because it has prevented a decline in abundance while continuing to provide fishermen with access to the resource. Only the herbivores, driven mostly by a 20% decline in the biomass of scarids, have decreased in the KNP as a whole since the re-zoning. The loss of herbivores is of particular concern given the important role these fishes have in maintaining reef resilience (Hughes et al 2007). However, similar trends in the biomass of each trophic group outside the KNP suggest that factors other than the re-zoning may be causing these patterns. For example, fishing effort as whole may have declined in the region as fishermen, encouraged by the efforts of the local government and supported by international NGOs, move into other livelihoods.

Interestingly, some of the zones have been more effective than others in preserving or increasing biomass. In particular, the biomass of all trophic groups, except herbivores, has increased in the Core Zone. Similarly, the biomass of all groups, except herbivores and omnivores, has increased in the Tourism Zone. In contrast, the Protection Zone has been much less effective at protecting biomass, with large decreases in the biomass of most trophic groups. This suggests that fishing effort has increased in the Protected Zones as a result of fishermen shifting effort from the Core and Tourism Zones. Further research, documenting both fishing effort and location of catch will be required to explain the difference in the effectiveness of these Zones.

Fish biomass within KNP is lower than comparable MPA's in Indonesia, for example, the biomass per hectare is 50–100% lower than in similarly managed areas in Aceh (Fig. 7) suggesting the area may be over-fished and current fishing effort unsustainable over the long term.

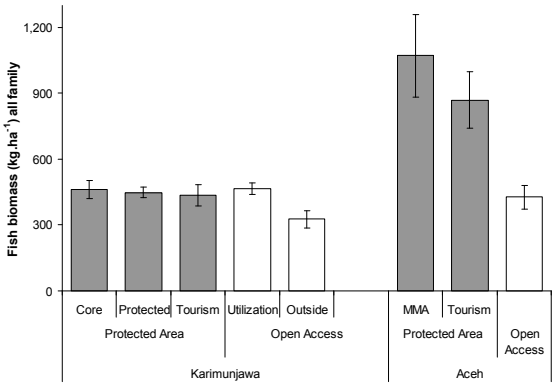

Figure 7. Mean (±SE) biomass (kg.ha^{-1}) of fish all family: comparison between Karimunjawa NP, and Aceh protected areas (Aceh Tourism and Aceh MMA).

The following recommendations have been made to the KNP authority

1. monitoring fish catch by documenting which fish are being caught and how many
2. evaluate fishing effort in each Zone and possibly restrict fishing gear especially nets
3. develop communication and awareness tools to enhance the perception of the benefits of marine parks in the local communities
4. patrol the KNP to measure compliance;
5. place more visible marking buoys to delineate Zones Boundaries to reduce non-compliance;

Community sea tenure and the establishment of marine reserve networks in the Pacific islands.

C.Y. Bartlett[1] C. Manua[2]

1) School of Earth and Environmental Sciences, James Cook University, Townsville, QLD, 4811 Australia
2) The Nguna-Pele Marine Protected Area Network, PO Box 8324, Vanuatu

Abstract Recent studies call for the scaling-up and networking of local marine reserves for ecological effectiveness and resilience. Currently, the Pacific islands are witnessing an explosion in the number of community-based marine reserves. Village sea tenure is the foundation for the development of reserves in the Pacific and likely poses a distinct challenge to coordinated marine management and networking. We examine the Nguna-Pele Marine Protected Area network in Vanuatu to understand how sea tenure may act as a barrier or advantage to multi-community reserve networking. We found that networks of community reserves may be practical in the Pacific islands if they address a locally-defined need and build on existing collaborative governance arrangements. Networking frameworks must flexibly match local sociocultural contexts. We conclude that networks of reserves do not necessarily usurp management or ownership rights but rather may strengthen and legitimize community sea tenure regimes in the Pacific islands.

Key words: Marine reserve, customary marine tenure, Vanuatu, taboo, marine protected area network

Introduction

There has been a recent call by marine scientists to scale up global marine management focus from single marine protected areas to representative and connective networks of marine reserves (Hughes et al. 2005). In the Pacific islands however, governance and decision-making institutions most commonly operate at the community level (Berkes 2009). Non-centralized governance and ownership poses significant implementation challenges for effective and well-coordinated marine reserve networks in the Pacific islands (Lam 1998).

Though much is written on the diversity of marine tenure arrangements and management practices utilized in the Pacific islands (Bartlett et al. 2009), few studies have empirically examined the characteristics that allow for successful cross-tenure networking initiatives. We present the Nguna-Pele Marine Protected Area network in Vanuatu as a case study to further understand the conditions that enable a network of marine reserves to function across community tenure boundaries.

Methods

We carried out this research on the islands of Nguna and Pele from 2005-2007. A team of local researchers conducted interviews with over 80% of the population in six study communities. Qualitative data on local sea tenure arrangements was collected via focus groups, transect walks, document analysis, participant observation and key informant interviews.

Results

Marine Tenure in the Pacific islands

The most authoritative definition of customary marine tenure was forwarded by Ruddle et al. (1992) where: "customary" refers to a system that emerges from firmly traditional roots and has continuous and meaningful links with the past as it adapts to handling contemporary issues; "marine" refers to the system as dealing with coral reefs, lagoon, coast and open sea and including islands and islets contained in this overall sea space; and "tenure" refers to a social process of interacting activities concerning control over territory and access to resources.

More recently Aswani's (2002) definition removes reference to historical practices and defines sea tenure as "a situation in which particular groups of people have riparian entitlement to nearshore areas, and in which their entitlements to use and access resources are excludable, transferable, and enforceable, either conditionally or permanently."

Case study context: Nguna and Pele islands

Nguna and Pele are islands (17ºS and 168ºE) in the central Shefa province of the Republic of Vanuatu.

Each island is surrounded by fringing reefs, typically extending from 10-200m from the shoreline.

Human settlement and organization

The population of Nguna and Pele was just over 1100 people at the time of the last national census (Bakeo et al. 2000), and is spread unevenly among sixteen communities, ten of which are located directly on the coast. No village is more than three hours walk from any other.

Since the time of missionaization of the two islands in 1870, there have been several major changes to human settlement; massive depopulation forced some villages to converge and move towards the coast while others were abandoned (Don 1918). The most important impact missionaries had in the Nguna-Pele area was their reorganization of local social structures; a shift from a clan-line elected system of governance to a hereditary royal-family chiefly system.

Today a hereditary paramount chief presides over each village, assisted in governance duties by one or more lower chiefs. The function of the chief largely deals with preservation and promotion of custom (Bolton 1998). Day to day affairs and administration of the community however, falls to the democratically elected village council as is common in other parts of the country (Huffer and Molisa 1999). The council apparatus is a direct artifact of the influence of the Christian Church, and is often made up of several specialized committees.

Terrestrial resource use and ownership

In Vanuatu all land belongs to customary owners by decree of the national constitution. However, the definition of customary ownership remains undefined and has partly led to the current legitimization crisis facing the nation (Nari 2000). In Vanuatu, customary land owners are not always (or even usually) individuals, a trait that existing statutory land policy does not appropriately capture (Regenvanu 2008). Group right of access to natural resources is the norm in Pacific island societies, and is especially relevant and commonplace in the marine context (Ruddle 1998).

Encouraged by regional policies and exacerbated by investor-driven land acquisition (Hassall 2005; Regenvanu 2008), there is a legal trend away from group and toward private land ownership in Vanuatu. On Nguna and Pele, land areas and garden plots currently have relatively clear boundaries, though ownership lies with extended families rather than individuals. However, few legal deeds have been granted over parts of these two islands.

Village boundaries are perceived differently to family land parcels. A strong sense of village-ism and community patriotism exists on Nguna and Pele. Belonging to a community or village is a critical safety net, protecting against need by ensuring access to resources for even those without hereditary entitlements. Thus, the geographical boundaries of a community hold utilitarian importance on Nguna and Pele, even though most families have access rights to land outside their own community. Village boundaries on Nguna and Pele commonly originate from the top of a hill and follow a well defined physical feature, such as a creek or stone wall, to the coast.

Due to the uncodified nature of a "community", and the dynamic settlement context since missionization on Nguna and Pele, village boundaries are typically unclear and commonly under dispute. Most villages have areas of overlapping boundaries with adjacent communities. An unremarkable fact of life for most residents, these disputes have occasionally flared up into hostilities when benefits of tourism or infrastructural development were at stake.

Despite infrequent tensions between communities, the Nguna-Pele area is locally renowned for its area-wide historical collaboration. Villages on the two islands share a unique dialect as well as similar cultural and customary practices. Intermarriage among island villages ensures social connections remain strong. Another legacy of the Church's presence is the existence of robust, duel-island networks like the Nguna-Pele Presbyterian Session uniting the elders from each community, and the Nguna-Pele Council of Chiefs (NAPE).

Marine resource use and ownership

Few individuals or households on Nguna and Pele make an exclusive living from the sea, though most are involved in opportunistic fishing and reef gleaning. Some coastline villages, those on Pele for example, have a more frequent interface with sea resources than their inland counterparts. Household diet of sea resources is variable on both islands, dependent on the capacity and time allocated to fishing by family members.

In stark contrast to land ownership, areas of reef are not partitioned off for use by particular families or groups. Reefs are open for use by all members of a given community, with residents feeling little desire to exclude their fellow community members. Regular access to marine resources may be an important motivation for seeking clear and well-recognized community boundaries.

Community access to marine resources is generally allowed, as long as it fulfills only

subsistence or small-scale commercial needs. Major developments, such as shoreline construction or large-scale commercial harvest, require permission of the chief and the village council. It is not uncommon for a village member to make a monetary contribution to the council when undertaking a larger-than-usual harvest from village sea tenure area.

Marine boundaries are inherently difficult to define, and there exist a myriad of perceptions on the local extent of sea tenure areas on Nguna and Pele. Some residents consider that the outer edge of the reef constitutes the extent of a village's sea tenure. Generally however, it would not be tolerated for an outsider to fish within several hundred meters of the edge of a village's reef. Accordingly, many consider the sea tenure boundary to extend well into deep water, with some citing the horizon.

Marine governance

Exclusion of non-community members from using village resources is a *de facto* practice on Nguna and Pele. Permission must always be sought before reefs can be used by an outsider. Full time residency is the most common, but not exclusive, determinant of community membership. One role of the chief is to grant or revoke permission for outsiders to use a community's reef resources. This right does not imply that the chief owns those resources, but only that he or she is symbolically responsible for reef stewardship. In practice, the village council holds daily responsibility to define the uses, developments and restrictions within the community's sea tenure area.

The Nguna-Pele area may be one of the most advanced in Vanuatu in terms of its general consciousness of natural resource management issues. Each community's village council has established a conservation committee, whose primary responsibility is the maintenance and regulation of terrestrial and marine resources. Conservation committees propose and adapt the specific rules for use of the reef. These committees report to and follow the mandates of the village council, who in turn work under guidance of the paramount chief.

It is considered everyone's responsibility, including residents, the conservation committee, village council and chiefs, to comply with village marine regulations and report trespassers. Enforcement and surveillance is not difficult in most cases as reef areas are visible from the village. However there are cases on Nguna and Pele where the reef is located away from the settlement area, and trespassing events are likely more frequent.

Breaking the rules generally invokes a fine payable to the chief, which is then divided among the council and conservation committee. Infractions that involve non-community members however, are dealt with directly by the chief or village council of each respective community. Fines for non-community members are generally higher as these offenses are viewed as more severe.

Tension and ambiguity characterize the relationship between village, provincial and national-level marine policies. While higher levels of government recognize local governance institutions though Island Courts and Land Tribunals, village councils do not receive formal endorsement in national legislation. The Environmental Management and Conservation Act recognizes marine regulations set by village councils, but does not provide for enforcement or penalization.

Fisheries closures

The closure of all or part of a community's sea tenure area is widely practiced in the Pacific islands (Caillaud et al. 2004). Closures employed in the past by communities on Nguna and Pele were generally enacted in order to stockpile resources in preparation for a celebration or community event such as a wedding or chiefly ordination. Closure duration was commonly pre-decided, with enactment and rescindment independent of the quality or quantity of resources available on the reef.

In contrast, recently established marine closures in the Nguna-Pele and surrounding areas are being established with the clear objective of resource maintenance or conservation (Bartlett et al. 2009). Residents acutely perceive the decline of marine resources on their tenured reefs, and are aware of the global state of marine resources. A conservation ethic is real and very apparent on the islands of Nguna and Pele despite ongoing debates regarding its historical existence in the Pacific (see Foale and Manele 2004).

Contemporary community reserves in the region are small, typically less than 0.05km^2, and cover from 15-45% of the available sea tenured area (Bartlett et al. 2009). Strong sea tenure is the ultimately the foundation for the establishment of community fisheries closures.

Diverse marine reserve expressions

Although the goals and objectives of individual marine closures are similar, their form and expression is extremely diverse among communities on Nguna and Pele. We found three marine closure deigns common in the Nguna and

Pele area: permanent, rotational and periodically harvested reserves (Bartlett et al. 2009).

Permanent reserves are those in which the community indefinitely closes all harvest. Rotational reserves do not permit harvest during their term but are designed to be permanently opened in the not-too-distant future. Periodic reserves may allow infrequent and well-controlled harvest at any time, but generally not more than one or two times per year. Reserves (of all types) commonly restrict all species enclosed within, though reserve openings and harvests may target specific organisms.

The decision to implement a marine reserve is nearly always taken democratically. The village conservation committee commonly makes the suggestion in a village meeting, followed by public debate among residents. If a closure is approved, residents discuss potential locations and the type to be implemented. Final approval by residents to declare a reserve can take up to a year of detailed planning by the conservation committee. Once approved, a date is fixed so that notices can be sent to adjacent villages and customary preparations made.

Marine reserve declaration is attended by customary ceremony. The village chief, as the symbolic resource steward, proclaims the area off limits following the terms set by the community. The paramount chief will generally evoke ancestral protection over the area, deterring future rule-breakers and trespassers. Often, several pigs are killed at the site. Boundaries of the closed area are demarcated with recognizable custom objects. On Nguna and Pele, a *namele* palm leaf tied to a stake is the most commonly-employed marker, though large white stones, pig jaws and painted signs are also used.

Networking of community marine reserves

In 2002, four paramount chiefs established the Nguna-Pele Marine Protected Area Network in order to better coordinate the management of their village marine closures. They felt that village strategies were ineffective in isolation; resources were declining at an unprecedented rate. With the technical and ideological assistance of the Fisheries Department, the Vanuatu Environment Unit and international volunteer organizations, the network's membership has since expanded to included 14 communities on Nguna and Pele.

The Nguna-Pele MPA network is locally managed by representatives from each member community. Membership is open to all communities on the two islands. A full-time local manager, several part-time local staff and local village volunteers carry out the day to day activities of the network. These activities include cleanup campaigns, awareness talks, sea turtle tagging, eco-tourism, tree planting, social and ecological monitoring and management evaluation.

The Nguna-Pele MPA network does not hold ownership or enforcement rights over the sea tenured areas of any of its village members, nor does it dictate the type of closure and associated rules to be implemented. Rather, the network brings together representatives from each community to discuss, coordinate and collaborate on marine and terrestrial natural resource issues of area relevance. Networking enhances the political bargaining power area communities have with the national and provincial government in terms of the support they receive for marine management.

The benefits of networking are locally recognized, with villages often willing to adopt management strategies that may be most valuable to neighboring, 'downstream' communities. For example, a recent crown of thorns starfish outbreak was contained because area representatives planned and implemented a cross-tenure clean-up strategy. Discussions at Network meetings have also influenced the positioning of new reserves, particularly at boundaries with other communities, in order to create larger cross-tenure reserves. This island wide collaboration represents Vanuatu's first attempt at ecosystem-level conservation planning.

Discussion

Community tenure potentially limits the establishment of marine reserve networks in the Pacific islands. However, the Vanuatu case demonstrates that despite strong tenure, cross boundary decision-making and influence can be achieved through local networking. We have shown how village sea tenure is maintained as resource governance is simultaneously scaled up. Several factors have facilitated the success of the Nguna-Pele MPA network, some of which may be applicable in other Pacific island contexts.

On Nguna and Pele, marine resources are perceived to be in severe decline, likely driving the need and motivation for collaboration among area villages. A networking and conservation ethic exists because residents have directly observed the frustrating ineffectiveness of individual village actions. Though not acting completely altruistically, communities have shown they are willing to compromise and collaborate to obtain at least some reprieve from the locally perceived marine crisis. Inclusive and representative policies minimize the potential that the network serves the interest of some communities over others.

Networking in this case study is locally supported as it flexibly incorporates different types and expressions of marine reserves, and integrates these within chiefly and ceremonial practices. It does not discriminate or attempt to force a single approach or strategy. The Nguna-Pele MPA network's structure emulates previously existing island-wide organizations, eliciting local trust and participation. Networking is enhanced because all member villages speak the same language, are geographically proximate and share a historical trajectory. Management and implementation by local people helps engender the support of other island residents.

The costs of scaled-up governance are minimized at Nguna-Pele as individual reserve maintenance remains firmly situated at the village level. Communities are empowered, and their managerial roles expanded, through the retention and adaptation of tenure-based models of management and enforcement. In other words, reserve management (and associated cost) remains decentralized, while simultaneously allowing for scaled-up cross-tenure coordination. While not directly implementing or managing reserves, the Nguna-Pele MPA network has a powerful indirect influence on area-wide management scope and connectivity.

Conclusion

We know that marine commons dilemmas can be solved at small scales (Berkes 2006), with community conservation areas an increasingly popular approach (Berkes 2009). However, this case study demonstrates that scaled-up collaborative marine governance is achievable in the Pacific islands without compromising community marine tenure and associated management rights. Networks of marine reserves may be a real possibility in the region if they address a locally-identified need and build on existing management and governance arrangements. Flexible networking frameworks are required that reflect local sociocultural contexts. Ultimately, strong village tenure can be an advantage for establishing effective marine reserve networks, and may be critical for scaling up marine governance in a region with limited centralized governance capacity.

Acknowledgement

This research is dedicated to the people of Nguna and Pele islands of Vanuatu. Fieldwork was assisted by a team of ni-Vanuatu collaborators led by W. & S. Kenneth. Funding and support was provided by the NOAA International Coral Reef Conservation Grant Program, the US Peace Corps, James Cook University and the Nguna-Pele Marine Protected Area network. We are especially grateful for ongoing support of the Vanuatu Fisheries Department and Environment Unit.

Abstract. Marine protected areas (MPAs) are important tools for management of marine ecosystems. While desired, ecological and biological criteria are not always feasible to consider when establishing protected areas. In 2001, the Virgin Islands Coral Reef National Monument (VICR) in St. John, US Virgin Islands was established by Executive Order. VICR boundaries were based on administrative determination of Territorial Sea boundaries and land ownership at the time of the Territorial Submerged Lands Act of 1974. VICR prohibits almost all fishing and other extractive uses. Surveys of habitat and fishes inside and outside of VICR were conducted in 2002-07. Based on these surveys, areas outside VICR had significantly more hard corals; greater habitat complexity; and greater richness, abundance and biomass of reef fishes than areas within VICR, further supporting results from 2002-2004 (Monaco et al., 2007). The administrative (political) process used to establish VICR did not allow a robust ecological characterization of the area to determine the boundaries of the MPA. Efforts are underway to increase amounts of complex reef habitat within VICR by swapping a part of VICR that has little coral reef habitat for a Territorially-owned area within VICR that contains a coral reef with higher coral cover.

Key words: Marine Protected Area, Coral Reef, Fishes, Overfishing

Introduction

Virgin Islands Coral Reef National Monument (VICR) is an MPA established by US President Clinton on January 17, 2001 under the Antiquities Act of 1906 (34 Stat. 225, 16 U.S.C. 431). These submerged lands consist of about 51 km^2 of marine habitat in five areas off the island of St. John, US Virgin Islands and are managed by the Secretary of the Department of the Interior through the National Park Service. VICR is comprised of many tropical marine habitats, including fringing mangroves, seagrass beds, nearshore coral reefs, a mid-shelf reef structure and deep water algal plains. Marine resources around St. John have declined dramatically over the past few decades (Rogers and Beets 2001, Beets and Rogers 2002). VICR was intended to enhance resources in the Virgin Islands and specifically in the Virgin Islands National Park (VINP), which was established by Congress in 1956 and expanded to include submerged lands in 1962. This new Monument roughly doubles the area in and around St. John now under the jurisdiction of the National Park Service (NPS). Provisions within the Presidential Proclamation prohibit all extractive uses with the exception of fishing for a coastal pelagic species, blue runner (*Caranx crysos*) south of St. John and bait fishing in a small area within the Coral Bay component of VICR (Fig. 1). In addition, boat anchoring is prohibited in VICR, except for emergency or authorized administrative purposes. The NPS, the National Oceanic and Atmospheric Administration (NOAA), and the US Geological Survey (USGS) initiated a joint project in 2002 to develop a baseline characterization of species and their associated habitats within and outside VICR to assess changes within the ecosystem. The project objectives have evolved to monitor the efficacy of the marine reserve and adjacent areas.

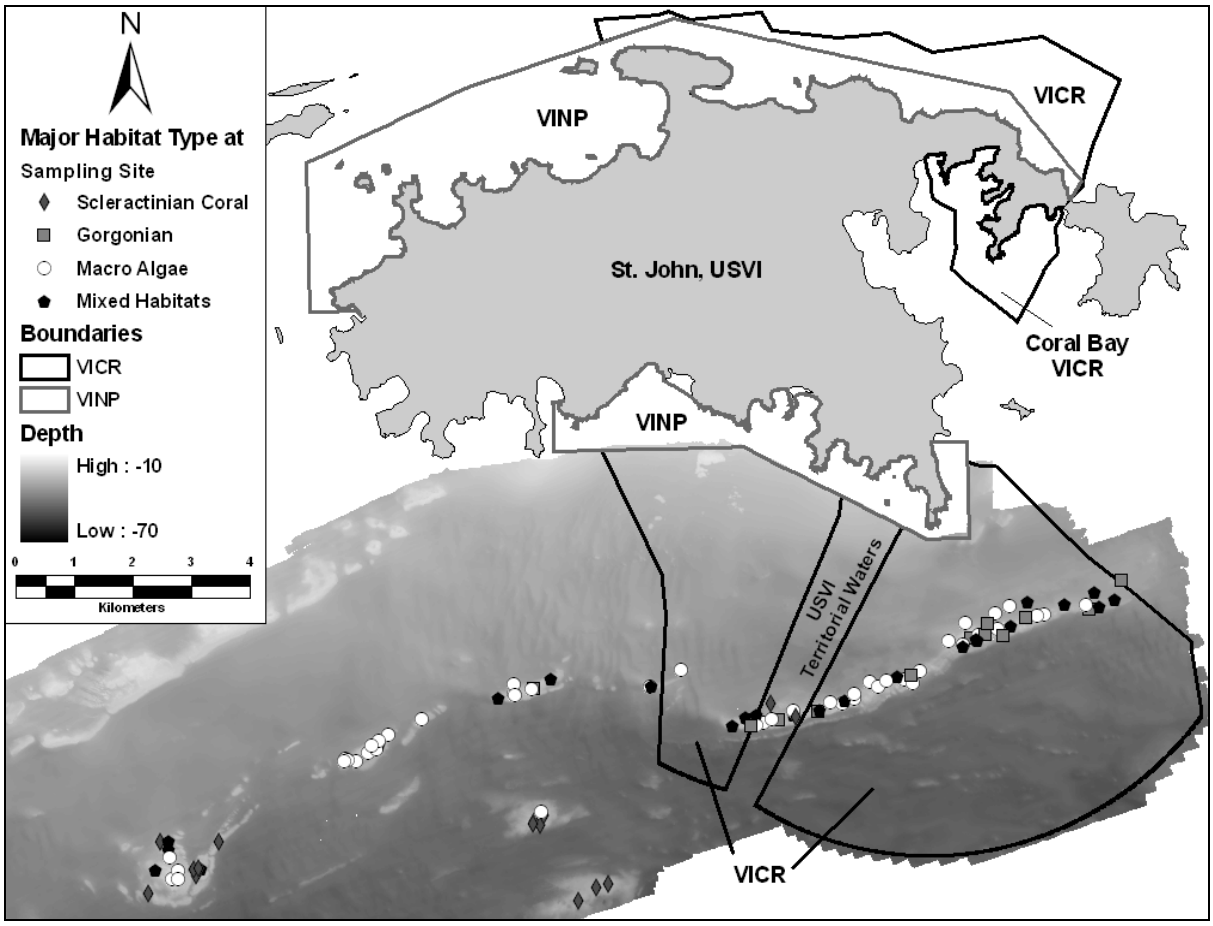

Figure 1. Boundaries of Virgin Islands National Park (VINP) and Virgin Islands Coral Reef National Monument (VICR). Symbols represent survey locations and major habitat types defined at each location.

Material and Methods

The mid-shelf reef is unique for St. John, owing to its relatively deep (17-35m) coral reef ecosystem and relatively high percent live coral cover and topographic complexity. Not all of the mid-shelf reef area is contained within VICR because the MPA was delineated based on legal parameters of the Submerged Lands Act that define federal waters. As a result, VICR is bisected by a wedge of submerged land that extends out from shore from privately owned lands that are not included in the VINP. Additionally, the mid-shelf reef extends to the west of St. John and south of St. Thomas.

Sampling sites were randomly selected inside and outside of VICR within the coral reef habitat of the mid-shelf reef. Modeled bathymetry derived from NOAA depth soundings was used as a surrogate to identify areas of potential coral reef habitat. Additional bathymetry data for water depths ranging from 20-100m for the area south of St. John (Fig. 1) were provided from multibeam surveys (2004-05) off the NOAA ship R/V *Nancy Foster*. Visual reef fish surveys were conducted annually in July from 2002 to 2007 and associated fine-scale habitat data were also obtained during the surveys. Fish abundance and size at each location were obtained on SCUBA via visual belt transect surveys (25x4m). A second diver assessed habitat quality (coral cover) and complexity (rugosity) within a 15-m diameter circular sampling area nested within the belt area. Both of these parameters are based on a visual estimation as defined by the rapid habitat assessment protocol with rugosity scaled from 1 to 3 (low to high).

Results

Habitat Comparisons

Although there was no significant difference in depth between management strata ($P>0.05$), there were differences between the benthic habitats inside vs. outside VICR (Table 1). Rugosity and live coral cover were greater outside VICR compared to inside VICR ($P<0.05$). The extent of hard bottom habitats outside VICR was greater than inside VICR. No sites within VICR were classified as having live scleractinian coral as a dominant biotic component (Fig. 1).

However, gorgonian cover was significantly higher inside VICR than outside (Table 1).

Table 1. Mean (±SD) benthic habitat characteristics inside and outside VICR along the mid-shelf reef south of St. John (2003-07). P is the probability of a significant difference between inside and outside VICR. Asterisk (*) indicates significant difference (P<0.05).

Habitat characteristic	Outside VICR mean (± SD)	Inside VICR mean (± SD)	% Differ-ence	P value
Abiotic				
Depth (ft)	87.76 (8.76)	87.03 (8.86)	-0.8	0.555
Rugosity	2.21 (0.66)	1.92 (0.81)	-15.1	0.007*
Hard bottom (%)	85.76 (9.654)	81.21 (23.89)	-5.6	0.07
Sand (%)	10.53 (7.97)	13.07 (16.59)	19.4	0.161
Rubble (%)	3.7 (4.09)	4.88 (11.49)	24.2	0.322
Biotic				
Live scleractinian coral cover (%)	18.41 (19.37)	4.46 (6.4)	-312.8	<0.001*
Gorgonian cover (%)	11.46 (7.87)	19.72 (14.8)	41.9	<0.001*
Macroalgal cover (%)	46.28 (18.83)	42.45 (21.84)	-9.0	0.18

Fish Assemblage Comparisons

Fish assemblage characteristics (species richness, numerical density, and biomass) differed significantly between management strata (Table 2), with all significantly greater outside VICR. Among the three habitat types represented both inside and outside VICR (gorgonian, macroalgae, and mixed coral), fish assemblage characteristics were not significantly different (Two-way ANOVA, P>0.05) for all.

Table 2. Comparison of mean (±SD) fish assemblage characteristics inside and outside VICR along the mid-shelf reef south of St. John (2002-07). P is the probability of a significant difference between inside and outside VICR. Density and biomass ln(x+1) transformed for statistical analyses. Asterisk (*) indicates significant difference (P<0.05).

Fish assemblage characteristic	Outside VICR mean (± SD)	Inside VICR mean (± SD)	% Differ-ence	P value
Species richness	27.05 (5.87)	23.0 (0.44)	-0.18	<0.001*
Density (indiv/100m^2)	307.92 (23.52)	215.79 (13.71)	-0.43	0.003*
Biomass (kg/100m^2)	10.49 (8.78)	8.21 (6.7)	-0.28	0.01*

Comparisons Among Major Fish Families (2002-2007)

- Total parrotfish biomass was 42% higher outside than inside VICR (Z=4.33, P<0.001). These species are important grazers on the reef
- Economically important groupers had 44% higher biomass outside VICR relative to inside (Z=2.33, P=0.02; Fig. 2)
- Fish biomass has increased inside VICR since 2005 primarily due to an increase in piscivores; however piscivores have declined outside over this same time period (Fig. 3)

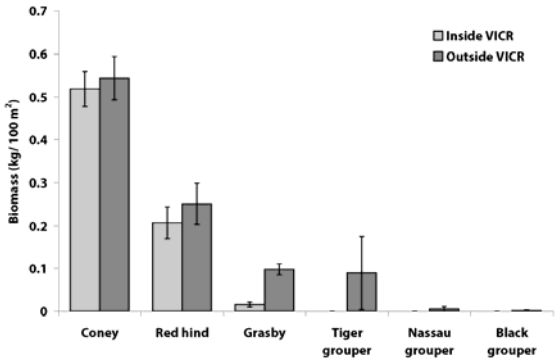

Figure 2. Mean biomass of an economically important fish family, groupers (Serranidae), inside and outside VICR (2002-07). Error bars represent standard error of the mean.

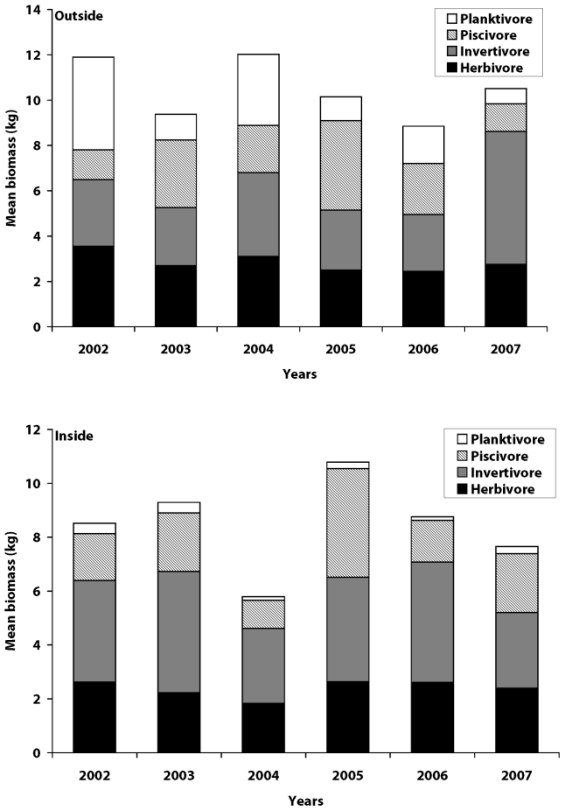

Figure 3. Biomass of trophic guilds outside (top) and inside (bottom) VICR.

Conclusions and Next Steps

The establishment of VICR was a politically driven process based on an exception in the Submerged Lands Act of 1974. As a result, much of the optimal coral reef and fish habitat on the mid-shelf reef is located both in the wedge and to the west of VICR.

Nevertheless, establishment of this MPA does provide for protection of the resources and may lead to resource enhancement over time, especially if an ecological correction can be applied.

While reef sites outside of VICR cannot be considered for inclusion an ecological correction can be made by exchanging the eastern, less biologically rich portion of VICR for the wedge of Territorial Sea that currently bisects VICR on the south side of St. John (Fig. 4a).

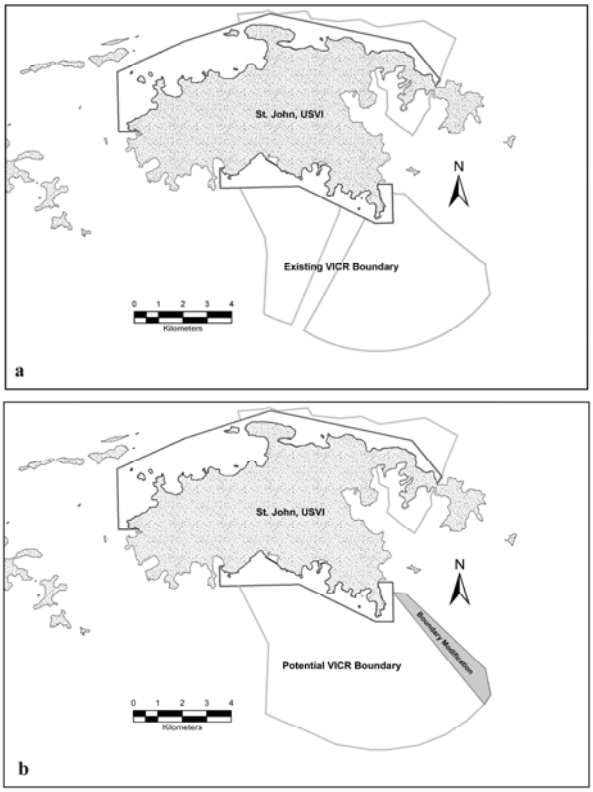

Figure 4. a) Existing VICR boundary and b) potential modification of VICR boundary along the south shore of St. John, USVI.

This process requires agreement from both Territorial and Federal governments in order to occur. The process was initiated before the election of a new VI Governor which delayed progress. The new Governor and the local Department of Planning and Natural Resources, along with many fishermen, have expressed support for the exchange. A recent meeting with the VI Delegate to Congress has resulted in a letter from the Governor to the Secretary of the Department of Interior requesting that negotiations begin for the exchange. As the wedge is already within the authorized boundaries of VICR, this should facilitate the boundary adjustment (Fig. 4b). The major issue will be an appraisal of the submerged lands to be exchanged, since no precedent exists for appraising deep water coral reefs and algal plain.

Inclusion of the mid-shelf reef currently located within the wedge will increase the amount of coral reef and fish habitat in the VICR and provide greater opportunity for resources in this MPA to recover from past harvest of resources and other stressors. This will also eliminate the concern of fishermen that they may be violating VICR regulations and will enhance enforcement of those regulations by NPS law enforcement rangers.

Coral reef ecosystems are threatened by natural stressors, human activities, and natural stressors exacerbated by human activities. Under the U.S. Clean Water Act, States and Territories may guard against anthropogenic threats by adopting water quality standards based on biological, physical, and chemical criteria. The condition of biological communities is a more dependable water quality standard than are physical and chemical attributes because living organisms are responsive to effects of low-level, chronic, cumulative, interacting point- and non-point source pollution. The President's Ocean Action Plan directed the U.S. Environmental Protection Agency (EPA) to develop biological assessment methods and tools for evaluating the health of coral reefs so that States and Territories could more easily establish biological water quality standards, including descriptions for designated waterbody uses and biological criteria (biocriteria). Biocriteria are qualitative or quantitative thresholds of biological condition necessary to sustain the designated uses. Rigorous biological assessments are needed to identify metrics that reflect biological characteristics and are responsive to a gradient of human disturbance, and to generate defensible long-term monitoring programs. Implementation of biocriteria for freshwater ecosystems has forged a process that can be adopted for coral reefs. EPA is fostering development of coral reef biocriteria through research, evaluation, and collaboration.

Key Words: bioassessment, biocriteria, Clean Water Act, coral reefs, U.S. EPA

Coral reef ecosystems are declining worldwide, threatened by a variety of human activities including polluted runoff from agriculture and land-use practices, over-fishing, ship groundings, coastal development and climate change, as well as by natural stressors such as tropical storms, bleaching and disease (Knowlton and Jackson 2008). Concern over the existing and impending threat of climate change on coral reef communities has been expressed (Richardson and Poloczanska 2008), but local anthropogenic sources also contribute directly to reef decline and can exacerbate climate change impacts (Mora 2008). Local managers have little control over climate change, but regional policies and local decisions for waterbody activities and watershed land use could substantially reduce anthropogenic stresses.

In the United States and its dependent territories there are a variety of management approaches and opportunities for reducing anthropogenic stresses to coral reefs. The National Oceanic and Atmospheric Administration (NOAA), the National Park Service (NPS) and U.S. Fish and Wildlife Service (FWS) function as natural resource custodians for coral reefs and commonly establish Marine Protected Areas (MPAs) to protect habitat from physical damage and to restrict fishing (e.g., no-take zones). MPAs can be reserved by federal, state, territorial, tribal, or local laws or regulations; federal MPAs have been established by NPS, FWS, and NOAA (National Marine Fisheries Service, National Estuarine Research Reserve System, and National Marine Sanctuary Program). MPAs restrict human activities in particular areas in order to promote non-consumptive and non-destructive uses of natural and cultural resources, such as coral reefs. Even outside coral reef MPAs, responsible fishery management may be promoted through fishing restrictions and habitat protection. Managers may employ additional tools, such as mooring buoys and informational programs to protect reefs from physical damage and pollution.

Recently, natural resource managers have initiated programs to support coral reef resilience, or potential for recovery from climate change events (e.g., Keller 2008). Some resilience goals include:

- Assurance that resilient species and habitats are well-represented and replicated throughout the coral reef ecosystem, and in particular, inside protected areas
- Protection of critical areas, such as fish spawning aggregations and nursery habitats
- Preservation of connectivity among reefs and their associated habitats.

Finally, the U.S. Environmental Protection Agency (EPA), under aegis of the Clean Water Act (CWA), is authorized to protect coral reefs and coastal zones from sediment, nutrients, contaminants or microorganisms introduced into water bodies from human activity. This protection can be achieved through a variety of programs to reduce sewage effluent, industrial contaminant releases, agricultural pesticides, nutrient applications, and riverbed stability. However, the full weight of the CWA has not been directly applied in coral reef protection. The CWA creates the opportunity for States, Tribes, and Territories to implement enforceable water quality standards based explicitly on the biological condition of coral reef communities.

U.S. Clean Water Act

The Clean Water Act (CWA) is the primary federal law governing water pollution control in the United States. The objective of the CWA is to restore and maintain the chemical, physical and biological integrity of the Nation's waters. There are several regulatory vehicles in the CWA to curb pollution, and these indirectly protect coral reefs. For example, the CWA provides controls for point (Section 402) and nonpoint (Section 319) pollution sources, and a strong foundation for attainment of aquatic life uses (Section 303). However, there is even greater potential to protect coral reefs by focusing designated uses and water quality standards explicitly on coral reef conditions.

The CWA requires that States, Tribes, and Territories define chemical, physical and biological expectations for water resources (i.e., water quality standards), monitor conditions regularly, and report whether those expectations are being met. Water quality standards include 1) designated uses, which reflect goals for the water body, 2) numeric and narrative criteria to achieve the designated uses, and 3) antidegradation policies to prevent deterioration of high-quality waters (Karr and Yoder 2004).

States and Territories establish designated uses based on the physical, chemical, and biological characteristics of the water body, its geographical setting, and at their discretion scenic qualities and economic values as well. Waterbodies can be protected for public water supply, for protection and propagation of fish, shellfish, and wildlife, and for recreational, agricultural, industrial, and navigational purposes. Designated uses can also be written to specifically protect coral reef ecosystems by further defining the desired biological attributes. This is particularly compelling for those jurisdictions with generic designated uses.

For example, some jurisdictions may have simply adopted water classes for designated uses: *Class A* waters might cover many of the generic uses described above (i.e., navigation, agriculture, drinking water, aquatic life protection) and would be considered higher quality waters in need of more stringent criteria than *Class B* and *Class C* waters. More specific language could be added to these legally binding narratives to characterize the biological goals for coral reef ecosystems. This could include the need to maintain the structure and function of coral reefs similar to the natural community or a condition similar to minimally impaired reference sites. Designated uses for coral reef protection could include specific goals, such as '*protection of reef fish spawning aggregations'*, or '*protection of coral taxa richness and community structure*'. While revision of designated uses can be a time-consuming process, it is well worth the benefits to coral reef protection. The Biological Condition Gradient (BCG), as described by Davies and Jackson (2006) can be applied to the development of designated uses for coral reefs. Physical, chemical and biological criteria establish thresholds, qualitative or quantitative, to benchmark the desired water quality necessary to support the designated uses. Biological criteria (biocriteria) are perhaps the most relevant to coral reefs, not only because they integrate multiple cumulative stressors, but also because biological measurements resonate with managers and stakeholders. Biocriteria, codified under CWA Section 304a, represent the agreed upon condition, attributes and services that society seeks to maintain. Biocriteria specific to coral reef condition are a necessity if valued reef attributes are incorporated into designated uses.

Biocriteria and several other aspects of the CWA rely on biological assessments (bioassessments), which directly measure the condition of one or more taxonomic assemblages (e.g., corals, fish) and the chemical and physical attributes that support those assemblages. Since the community of plants and animals reflect the underlying health of the waterbody in which they live, assessments of species richness, species composition, population size, and trophic

composition of resident biota are the most direct measures of biological integrity (Karr 1991).

To implement quantitative (numeric) biocriteria, States and Territories must determine the biological conditions that sustain the designated uses, select measurements that reflect the relevant biological conditions (e.g., range, variability and responsiveness to human disturbance), and establish a defensible long-term monitoring program (Jameson et al. 2001). Coral reef biologists have a strong history of bioassessments and monitoring, and have developed biological indicators that might ultimately serve as biocriteria metrics, including:

- live coral coverage
- proportion of species tolerant to stressors of concern (e.g. pH, nutrients, temperature, sediments, metals, pathogens, etc.)
- number of species (taxa richness)
- proportion of exotics
- prevalence of disease
- percent recent mortality
- coral recruitment

Waterbody Attainment or Impairment

The CWA provides several different regulatory vehicles to curb pollution and thereby protect coral reefs. Section 305(b) of the Clean Water Act requires each State to prepare a biennial report on the quality of its waters. A 305(b) report describes the extent to which waterbodies support their designated uses. The report also identifies the pollutants or stressors causing impairment of designated uses and the sources of these stressors (e.g., wastewater treatment plants, agriculture, or industrial plants). EPA transmits the individual 305(b) reports to Congress along with a summary report on the Nation's water quality prepared using the 305(b) information. A well-prepared, scientifically sound 305(b) report can be beneficial to coral reef managers in these ways:

- The 305(b) report is a public information tool documenting State/Tribal/Territorial actions to protect waterbodies; it increases the visibility of the water quality programs.
- The report can call attention to special issues such as loss of critical fish spawning aggregation areas or coral reef habitat.
- The process offers an opportunity for State/Territorial technical staff to coordinate assessments and data management for shared waters.

Section 303(d) of the Clean Water Act requires each State and territory to periodically prepare and submit a list of specific waterbodies that currently violate or have the potential to violate water quality standards, including designated uses and numeric or narrative biocriteria. These lists must prioritize the waterbodies for development of Total Maximum Daily Loads (TMDLs). TMDLs identify the maximum amount of a pollutant that a waterbody can receive and still safely meet water quality standards, and allocate that amount among various sources (e.g., nutrient loads could be allocated between agriculture and sewage systems).

Comprehensive Strategy to Address Impaired Waters

It is a clear benefit of a biocriteria program that each monitoring cycle automatically triggers a regulatory decision (e.g., 303(d) listing requires priority rankings and development of TMDLs). Potential regulatory actions that managers can implement include:

- Increase the scope of National Pollutant Discharge Elimination System (NPDES) permits to incorporate bioassessments and biological thresholds
- Establish marina pumpout facilities and no discharge zones
- Implement new permit requirements (i.e., require that commercial and recreational boaters hold pollution discharge permits covering deck and hull cleaning, fueling, trash management, and graywater discharges)
- Require dischargers to evaluate wastewater reuse and recycle options or install more advanced technology

There are also non-regulatory, Best Management Practices that managers can choose to implement, such as:

- Agricultural (runoff control, grass/riparian buffers, manure management, conservation tillage, etc.)
- Urban and residential (upgrade sewer and water infrastructure, xeriscaping, pesticide management, riparian buffers, etc.)

Coral reef protection calls for integrated, collaborative management. Clear, shared objectives and improved coordination of programs are a necessity. States and Territories can adopt a watershed approach to managing coral reefs, where community officials, industries, environmental groups, and citizens throughout the watershed basin jointly identify the problems and develop priorities and actions to address them. By effectively managing watersheds, we can protect both the health of coral reefs and the people who depend on them. The CWA regulatory vehicles, including biocriteria, provide watershed-based management options to protect coral reef ecosystems that complement existing natural resource management.

EPA's Biocriteria Outreach

While the responsibility for establishing water quality standards lies with the States and Territories, EPA is providing support to define conservation and management needs, refine designated uses, develop bioassessment procedures and monitoring strategies, establish reference conditions and biological thresholds, differentiate anthropogenic from natural causes of change, and identify causes of adverse effects.

Over the last 20 years, EPA has developed a body of work to support implementation of biocriteria protective of freshwater and estuarine ecosystems (e.g., EPA 1996, 1998, 2000). Ongoing research (http://epa.gov/bioindicators/coral/) will help develop comparable opportunities for coral reefs.

Current Efforts of States and Territories

The U.S. Coral Reef Task Force has identified the need for local action to reduce key threats to coral reefs and called for the development of Local Action Strategies (LAS) in each of the seven states and territories that possess significant coral reef resources. While no LAS specifically addresses biocriteria, each is focused on improving water quality and coral reef condition through better understanding of the links between land-based pollution and coral reef health; improving compliance and enforcement of laws, rules, and regulations related to construction and land development permits; and implementation of best management practices to reduce pollution from agricultural and residential areas. Specific biocriteria-related activities of the States and Territories include:

American Samoa and the Commonwealth of the Northern Mariana Islands (CNMI): New narrative biocriteria have been proposed that include coral species richness (Houk et al. 2005). CNMI received an EPA Wetlands Program Development Grant to support the development of numeric biological criteria for coral reefs, and American Samoa is in the process of evaluating four measures as potential coral biocriteria: 1) coral diversity per unit area, 2) total coral diversity, 3) coral community evenness, and 4) a benthic substrate ratio.

Florida: An established quality assurance process is in place to ensure that data for Clean Water Act purposes are properly and consistently collected. Florida's Department of Environmental Protection has begun to identify and evaluate protocols that could be applied as biocriteria, beginning with EPA's Stony Coral Rapid Bioassessment Protocol (Fisher 2007).

Hawai'i: EPA is funding a wetlands grant to devise biocriteria based on the Hawai'i Coral Reef Assessment and Monitoring Program (Jokiel et al. 2004).

US Virgin Islands (USVI): Designated uses are being revised to include more specific biological attributes, and EPA is assisting USVI's Department of Planning and Natural Resources to design an integrated monitoring program to assess coral reef condition (Fisher et al. 2008).

Summary and Conclusions

Thus several US jurisdictions now recognize that the CWA provides a suite of powerful regulatory tools that can be applied to protect coral reefs. The process to establish a biocriteria program has been vetted in both freshwater and estuarine programs, and can also be applied to coral reefs. Coral reef biologists have knowledge and expertise, as well as a strong history of monitoring and assessment. They have also developed biological indicators that could ultimately serve as biocriteria metrics for supporting assessment of coral condition relative to the set standards, and for implementing regulatory or non-regulatory corrective action. Development of biocriteria is not easy, but many of the tools are available. With strong collaborative effort, we can successfully develop and apply biocriteria to protect U.S. coral reefs.

The development and implementation of coral reef biocriteria can also be incorporated into Water Quality and Coral Reef Programs outside the US and its territories. For example, the Coral-based Indicators of Changes in Water Quality on Nearshore Coral Reefs of the Great Barrier Reef (Cooper and Fabricius 2007) may be candidates for biocriteria to determine if Australian and New Zealand waters meet their beneficial use "Maintain health of aquatic ecosystems". In addition, the Healthy Mesoamerican Reef System Initiative has developed a suite of ecological indicators for coral reef ecosystems that may serve as biocriteria for Mexico, Belize, Guatemala, Honduras, Nicaragua and El Salvador (McField and Kramer 2006).

Abstract. Brazilian coral reefs have many endemic species. In the state of Alagoas, coral reefs are abundant, but different human impacts occur when the reefs are located in urban settings. This study compared the diversity of macrobenthic organisms on five coral reefs on the urban coast of the city of Maceió, which are subject to different human impacts. Semi-quantitative estimates of the abundance of live specimens at each station on these reefs consisted of visual records obtained during five full low-tide periods from 2005 to 2007. Fifty taxa of macrobenthic organisms were analyzed, using cluster analysis (UPGMA, Bray-Curtis). The Jatiúca (50 species) and Ponta Verde (50 species) coral reefs were similar, with 0.2 for cluster analysis; both sites are impacted only by harvesters of seafood. The Pajuçara (48 species) and Amores (47 species) coral reefs were similar, with 0.4 and 0.5, respectively; human impacts at these sites also include boat anchoring. Piscina Natural coral reef had the fewest macrobenthic species (13), with 0.7 for cluster analysis; human impacts on this reef include tourist activities and boat anchoring. These results call for stricter control of human impacts on coral reefs situated on the urban coast, and demonstrate that macrobenthic organisms can be useful indicators for monitoring coral reefs.

Key words: Brazilian reefs, invertebrate reefs, urban reefs, human impacts

Introduction

The Atlantic region is divided into four reef provinces; the Brazilian province is quite distinct because of its small number of coral species. Many of these species are endemic (Veron 1995), and are thus important for reef conservation. The first reports on coral reefs from Brazilian coast were by Laborel (1965, 1969a, b), who characterized scleractinian corals and hydrocoral zonation for different reefs along this coast. He also mentioned the impacts by many lime kilns, locally called "caieira," which exploited coral to obtain whitewash to correct the soil pH for sugarcane agriculture. The northeast coast of Brazil has the largest concentration of reef ecosystems, starting from the Manuel Luiz Banks in the state of Maranhão (Amaral et al. 2007) to the Abrolhos area on the south coast of the state of Bahia (Hetzel and Castro 1994). On the Abrolhos reefs, the species diversity and zonation patterns of hermatypic corals on two fringing reefs was studied by Pitombo et al. (1988), and the colonization and growth of crustose coralline algae were characterized by Figueiredo (1997). Castro and Pires (2001) noted that relatively little information exists about Brazilian coral reefs. Shallow-water scleractinian corals and Zoanthidea from the Coroa Grande reefs in the state of Pernambuco were characterized by Neves et al. (2002) and those from Itacolomi reefs in southern Bahia were characterized by Castro et al. (2006), who demonstrated differences in cover composition and species abundance along the northeast coast of Brazil. The marine sponge fauna of the Pernambuco coast is similar to that of other areas on the northeastern Brazilian coast, according to Muricy and Moraes (1998).

Belém et al. (1986) described environmental problems on coral reefs along the Brazilian coast, and called attention to some of the human impacts. Some reef ecosystems are being degraded by tourism in several areas, where there is a high intensity of activities because of the large flow of people and the lack of adequate planning. The environmental impacts caused by human activities on reef ecosystems were studied in the Abrolhos area (Coutinho et al. 1993, Leão et al. 1994, Leão 1996) and Fernando de Noronha island (Maida et

al. 1995), demonstrating that environmental degradation was linked to uncontrolled tourist activities.

On the coast of the state of Alagoas, environmental aspects and a general characterization of coral reefs, including faunal diversity, were presented by Sovierzoski and Correia (1995). Coral reefs are abundant on the Alagoas coast, and in some areas, fringing reefs are located near the beach line where the top of the reef platform is exposed during low tides. On these reefs, different human impacts occur, principally at urban sites, which are often visited by hundreds of people including local seafood harvesters and tourists, and are also used for boat anchoring (Correia and Sovierzoski 2005). The composition of the fauna associated with the different phytal areas was studied by Santos and Correia (1994, 1995, 2001), who demonstrated the great diversity of invertebrate species. On the Alagoas reefs, some information about species diversity and ecological aspects were described for the phylum Porifera (Sarmento and Corrreia 2002; Cedro et al. 2007). The first record of a living catenicellid bryozoan in the Atlantic Ocean was given by Vieira et al. (2007), from coral reefs on the Maceió coast.

The present study compared the effect of human impacts on the macrobenthic diversity in the intertidal zone, for five coral reefs situated on the urban coast of Maceió city, Alagoas.

Materials and Methods

The study area is situated on the urban coast of Maceió city, capital of the state of Alagoas, northeastern Brazilian coast, where there are many coral reefs (Fig. 1).

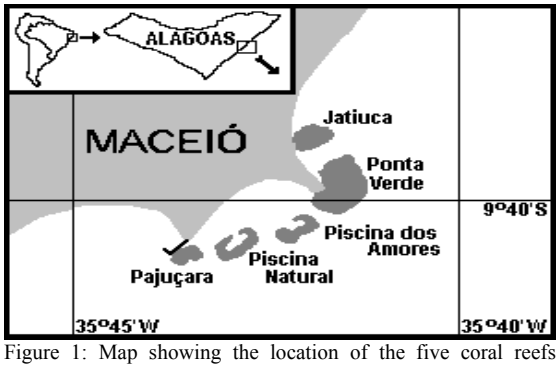

Figure 1: Map showing the location of the five coral reefs investigated on the urban coast of Maceió city, Alagoas, Brazil.

The present research was carried out in the intertidal zone on five urban coral reefs on the Maceió coast, where different human impacts occur. Some of these fringing coral reefs are located adjacent to the beachline, such as Jatiúca coral reef (9º39'38''S / 35º42'05''W), Ponta Verde coral reef (9º40'10''S / 35º41'30''W) and Pajuçara coral reef (9º42'18''S / 35º43'36''W). Two other coral reefs, Piscina dos Amores coral reef (9º41'18''S / 35º42'24''W) and Piscina Natural coral reef (9º41'48''S / 35º42'10''W), are situated at different depths in the offshore zone (Fig. 2).

All five coral reefs have the platform top exposed during low tide, where some macrobenthic organisms occur. However, the species are more concentrated in the reef pools, which are up to 2 meters deep. The reef borders have countless irregularities, with small entrances and some inlets with an accumulation of sand in the low areas, and strong wave and current action.

Semi-quantitative estimates of the abundance of live specimens on five transects, each 10 metres long, were made for the intertidal zone and in the reef pools of the five coral reefs. These estimated were based on an exhaustive compilation of visual records made during five full low-tide periods from 2005 to 2007. Fifty taxa of macrobenthic organisms were analyzed: 17 Porifera, 10 Cnidaria, 9 Echinodermata, and 14 macroalgae, because these organisms were the most common on these reefs. These macrobenthic organisms were selected because they are most common on the reef intertidal zone at Maceió coast. The macrobenthic analyses were based on the percentage cover for each species, showing the colonization intensity.

Figure 2: Aerial view of the coral reefs investigated on the urban coast of Maceió city, Alagoas, Brazil: (A) Jatiuca, (B) Ponta Verde, (C) Piscina dos Amores, (D) Piscina Natural, (E) Pajuçara.

On the urban coral reefs of Maceió, different human impacts occur: some areas are frequently visited by hundreds of people during low tide, principally in summer. The principal human

activities are local seafood harvesters, boat anchoring, and tourists, with different intensities depending on the number of people and boats per day during low tide that were transformed percentage occurrence. The Bray-Curtis index and UPGMA were measured for cluster analysis, to determine the similarity between macrobenthic organisms on the five reefs on the urban coast of Maceió city.

Results

There was an inverse relationship between the level of macrobenthic diversity and the level of human impacts at these sites. On the Jatiúca and Ponta Verde coral reefs, all of the 50 species of macrobenthic organisms were found (17 Porifera, 10 Cnidaria, 9 Echinodermata and 14 macroalgae). On the Pajuçara coral reef, 48 species were found; and 47 species were recorded for Piscina dos Amores coral reef. The Piscina Natural coral reef differed the most, with only 13 species, mostly macroalgae (Table 1).

Different intensities of human impact were recorded on the five coral reefs on the urban coast of Maceió city. All these coral reefs are usually visited by hundreds of people, such as local seafood harvesters, boat anchoring, and tourists, with differing intensities. On the Jatiúca and Ponta Verde coral reefs, few human impacts were observed, mostly seafood harvesters. On the Pajuçara and Piscina dos Amores coral reefs, human impacts were also caused by anchored boats. The Piscina Natural coral reef was subject to the highest level of tourist activities and boat anchoring, which occurs intensely year-round, principally in summer and vacation periods (Table 2).

Table 2: The intensity of human impacts on the five coral reefs investigated on the urban coast of Maceió city, Alagoas, Brazil. Legend: XXXX 100%, XXX < 75% , XX < 50% , X < 20%

	CORAL REEFS				
HUMAN IMPACTS	Jatiuca	Ponta Verde	Pajuçara	Piscina dos Amores	Piscina Natural
Seafood harvesters	XXX	XXX	XXX	XXX	XXX
Boat anchoring	X	X	XX	XX	XXXX
Tourists activities	X	X	X	XX	XXXX

Jatiúca and Ponta Verde coral reefs were more similar, with distance 0.2 in cluster analysis, where there was high diversity and low human impacts intensities were found. The Pajuçara and Piscina dos Amores coral reefs were included in the same cluster, with 0.4 and 0.5, but had fewer species and more human impacts. The greatest difference was observed on the Piscina Natural coral reef, with 0.7 for cluster analysis; there were few species, and the human impacts were caused by many different activities, as well as the presence of tourists (Fig. 3).

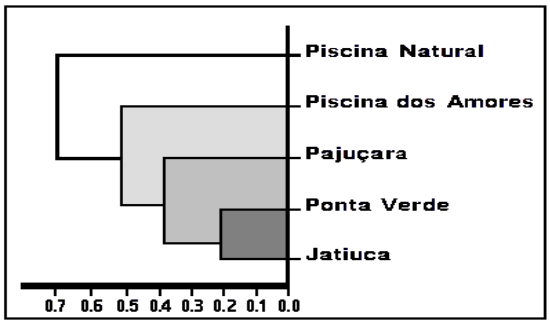

Figure 3: Cluster analyses on the five coral reefs investigated on the urban coast of Maceió city, Alagoas, Brazil.

Discussion

These results demonstrate that the diversity of macrobenthic organisms can be useful for monitoring coral reefs on the Brazilian coast, to discern the various levels of human impact. The coral reefs on the urban coast of Maceió city have many problems caused by human activities. Previous reports have described the different human impacts on coral reefs of the Brazilian coast, such as the studies of Laborel (1969a, b), who mentioned the whitewash industry, commonly referred to as "caieira", although this activity no longer exists.

However, this study indicates that there are more problems related to human impacts associated with tourist activities, which cause serious damage to the Maceió coral reefs. At all these sites, the scleractinian corals were most sensitive to different impacts among other macrobenthic organisms analyzed.

The results demonstrated differences in composition and species abundance along the northeast coast of Brazil, compared to information from Manuel Luiz Banks in the state of Maranhão (Amaral et al. 2007) and the Abrolhos area (Pitombo et al. 1988). However, on the Maceió coral reefs, the cnidarian species cited in this study are common on other coastal coral reefs in southern Pernambuco (Neves et al. 2002) and Bahia (Castro et al. 2006), as are the sponge

species on the coast of the state of Pernambuco (Muricy and Moraes 1998) and on the Maceió coast (Cedro et al. 2007).

On the impacted coral reefs, macroalgae occupy the substrate (Lirman 2001, McCook et al. 2001), because they grow faster than the invertebrate species such as corals and sponges. The evidence of this competition was found principally on the highly impacted Piscina Natural coral reef, with algae dominance and few invertebrate species.

Many other coral reefs areas along the Brazilian northeast coast have similar problems caused by human impacts (Belém et al. 1986, Coutinho et al. 1993, Maida et al. 1995). In all these reef areas, such as the Pisicna Natural coral reef, the highest impact level is caused by tourist activities, because they are visited by large numbers of people, principally during the summer vacations.

These observations illustrate the need for stricter control of human activities on urban coral reefs on the Maceió coast, with monitoring activities and restricting access, specifically in the coral reef areas where tourist activities occur.

Session Number 23

The U.S. Coral Reef Task Force: A Model for Fostering Coral Reef Management at National to Local Scales

E. Dieveney[1] and R. Griffis[2]

[1]National Oceanic and Atmospheric Administration, Office of Ocean and Coastal Resource Management, Coral Reef Conservation Program, Silver Spring, MD 20910. [2]National Oceanic and Atmospheric Administration, National Marine Fisheries Service, Office of Habitat Conservation, Silver Spring, MD 20910

This report assessed the strengths and weaknesses of U.S. Coral Reef Task Force (USCRTF) efforts to mobilize U.S. coral reef conservation at local to national levels. The success of the USCRTF has been its ability to bring together government entities with diverse and potentially conflicting mandates to identify common national goals and increase on-the-ground efforts addressing local and national coral reef conservation priorities. The USCRTF includes 12 U.S. Government agencies, seven states and territories, and three Freely Associated States. Through this broad membership, the USCRTF is uniquely situated to promote a holistic, ecosystem-based approach to coral reef conservation. The USCRTF developed the first *U.S. National Action Plan to Conserve Coral Reefs* and the *National Coral Reef Action Strategy* to define and direct its overarching goals, objectives, and activities. The national goals were further refined into place-based Local Action Strategies (LAS) to address six priority threats. The LAS provide a framework for USCRTF members to address national goals through on-the-ground action. While the USCRTF has significantly advanced U.S. coral reef conservation efforts, some key challenges include the inability to set clear conservation goals, targets, schedules and performance metrics, an imbalance of time spent on developing conservation plans rather than focused effort on implementing on-the-ground action, and little power/progress to stem the tide of government sponsored actions impacting reefs.

Key Words: U.S. Coral Reef Task Force, Local Action Strategies, coral reefs, conservation

Introduction

The United States Coral Reef Task Force (USCRTF) was established in 1998 by Presidential Executive Order 13089 to lead, coordinate, and strengthen U.S. government actions to conserve coral reef ecosystems; both domestic and international. The Executive Order recognizes the value of coral reef ecosystems and directs the U.S. Government agencies to work independently "to ensure actions they authorize, fund, or carry out will not degrade the conditions of such ecosystems." To fulfill this mission, the USCRTF develops national strategies, targeted initiatives, and new partnerships to strengthen stewardship of the coral reef ecosystems in the United States and internationally.

USCRTF membership includes leaders from twelve Federal agencies, seven states, territories, and commonwealths, and three Freely Associated States (See Fig. 2). To implement the policies and requirements of the Executive Order, the USCRTF provides a forum for collaborative planning, priority-setting, partnership building, and action among federal agencies, state and territorial governments, and non-governmental partners. The unique success of the USCRTF has been the ability to bring together government entities with diverse mandates and expertise to identify national goals and foster work at the regional and jurisdictional level that addresses both local and national priorities for coral reef conservation.

National Level Collaboration

The USCRTF developed the first U.S. *National Action Plan to Conserve Coral Reefs* (2000) and the *National Coral Reef Action Strategy* (2002) to identify and develop an implementation strategy for national coral reef conservation goals and objectives (see Fig. 1). To implement the *National Action Plan* and *National Action Strategy*, the USCRTF has supported a variety of actions to reduce adverse impacts to coral reef ecosystems, raise the profile of coral reef issues and increase awareness of the threats facing these valuable ecosystems. Some examples include:

The USCRTF has committed to produce comprehensive digital maps of all U.S. shallow-water

Figure 1: ***U.S. National Coral Reef Action Strategy***
13 Goals for Addressing Threats to Coral Reefs:

THEME 1: Understand Coral Reef Ecosystems—
Goal 1: Create comprehensive maps of all U.S. coral reef habitat.
Goal 2: Conduct long-term monitoring and assessments of reef ecosystem conditions.
Goal 3: Support strategic research to address the major threats to reef ecosystems.
Goal 4: Increase understanding of the social and economic factors of conserving coral reefs.

THEME 2: Reduce the Adverse Impacts of Human Activities—
Goal 5: Improve the use of marine protected areas to reduce threats.
Goal 6: Reduce adverse impacts of fishing and other extractive uses.
Goal 7: Reduce impacts of coastal uses.
Goal 8: Reduce pollution.
Goal 9: Restore damaged reefs.
Goal 10: Improve education and outreach.
Goal 11: Reduce threats to coral reef ecosystems internationally.
Goal 12: Reduce impacts from international trade in coral reef species.
Goal 13: Improve coordination and accountability.

(less than 30 meters) coral reef habitats, and to characterize priority moderate-depth (30-200 meters) reef systems. Completed digital map products cover 6,340 square kilometers of U.S. shallow-water coral reef ecosystems.

The *National Action Plan to Conserve Coral Reefs* calls for the development of a report on the state of U.S. coral reef ecosystems. These reports, The State of Coral Reef Ecosystems in the United States and Freely Associated States, produced in 2002, 2005, and 2008, characterize the condition of shallow-water coral reef ecosystems based on quantitative results of assessment and monitoring activities conducted by Federal, state, territory, commonwealth, non-governmental, private, and academic partners.

The USCRTF works to build capabilities to address such ecosystem-scale threats as disease, bleaching, and other sources of mass mortalities. To help meet this objective, the Coral Disease and Health Consortium (CDHC) was created in 2002 to provide coastal and ocean managers with scientific understanding and tools to help address coral health issues and mitigate degradation. The CDHC is a network of field and laboratory scientists, coral reef managers, and agency representatives devoted to understanding coral health and disease. It is cross-disciplinary, highly collaborative, and completely voluntary. Over 100 partners—including the Environmental Protection Agency, Department of the Interior, NOAA, other Federal agencies, academia, non-profit organizations, and industry—contribute their time and expertise

In 2005, coral reefs in the wider Caribbean suffered a widespread and severe bleaching event, which resulted in extensive coral death in much of the region. The USCRTF passed a decision item in November 2005 to mobilize efforts across the Caribbean to monitor, assess, and research short- and long-term impacts of the 2005 warming and bleaching event. The USCRTF Bleaching Committee coordinated the efforts of NOAA, NASA, the Department of the Interior's USGS and NPS, other government agencies, non-governmental organization partners, university researchers, and local managers.
The USCRTF acknowledges that marine protected areas (MPAs) are an important coral reef management tool, and has taken measures to incorporate this tool into their marine resource management efforts. The USCRTF called for strengthening the Nation's existing network of MPAs with particular attention to increasing the number of "no-take" marine reserves—areas where extractive uses are prohibited—and designing coordinated networks of coral MPAs in U.S. waters and other areas to ensure the long-term viability, ecological integrity, and sustainable use of coral reefs. The USCRTF has taken measures to assess how effectively this tool has been applied and USCRTF members have taken action to use MPAs to protect coral reef ecosystems.

Linking National Goals to Local Action – Local Action Strategies
While the USCRTF as a whole continues to make progress on the national goals, through a parallel and complementary effort these goals were further refined to focus on local, place-based issues. In 2002, the USCRTF developed place-based Local Action Strategies (LAS) which are designed to address priority threats at the local, jurisdictional level. The LAS provide a framework for USCRTF member agencies to identify and address priority threats and additional local needs, connect local priorities to national goals, coordinate Federal agency actions with local management of reef resources, and increase collaboration and resources to implement conservation actions. This approach allows the USCRTF members to tailor their goals and activities to address local issues and support on-the ground action.

Through the LAS process, the following priority threat areas were identified from the U.S. *National Action Plan to Conserve Coral Reefs* (2000):

- over-fishing,
- land-based sources of pollution,

- recreational overuse and misuse,
- lack of public awareness, and
- climate change, coral bleaching and disease.

Further, three jurisdictions used the LAS process to identify additional specific conservation issues and concerns for local action. These issues are:

- Maritime Industry and Coastal Construction Impacts – Florida,
- Invasive Species – Hawaii, and
- Overpopulation – American Samoa.

A *Status Report on Implementation of the Local Action Strategies* covering the fiscal years 2002 to 2006 identified approximately 760 projects across the seven jurisdictions and reports that the LAS have generated $25 million from numerous government and non-governmental sources applied to project implementation to date. Local agencies have leveraged hundreds of thousands of additional finds through volunteer services and in-kind resources, including time and skills, which have not been quantified in the total amounts of support received.

Local Place-Based Conservation Action

The ten USCRTF jurisdiction members span a vast geographic area, each with their own distinct set of issues, priorities, and stakeholder communities. The LAS framework has been specifically designed and used in each of the U.S. State, territory, and Commonwealth jurisdictions to address a particular set of issues and to meet the needs of the local community.

Two LAS examples follow, from Florida and Hawaii, which illustrate the value of and flexibility inherent in the LAS process.

Florida

Florida's LAS process serves as a model for the flexibility and specificity that the LAS structure allows. To meet a very specific management challenge, Florida developed the *Maritime Industry and Coastal Construction Impacts (MICCI*) LAS. Florida, more than any of the other USCRTF jurisdiction partners, experiences intense coastal use, development, shipping activity, and has an active network of commercial ports. This LAS is, therefore, intended to address activities such as vessel anchoring and groundings, infrastructure installation (e.g., cables, pipelines, and outfalls), beach nourishment, and dredge and fill operations in and around coral reefs and coastal habitats that can adversely affect these sensitive ecosystems. The key goals and objectives of the MICCI Focus Team are to:

1. Evaluate existing coastal construction and marine industry practices and their potential (or documented) impacts, and develop alternative or innovative methods and processes that significantly minimize or eliminate those impacts to marine habitats.
2. Compile and/or develop appropriate procedures for response to reef impacts, and reef restoration and monitoring.
3. Review existing regulations and suggest modifications or promote new regulations (as appropriate).
4. Encourage compliance with existing regulations.

Lack of awareness and knowledge of construction practices that can minimize these impacts is a significant source of the continued degradation of the southeast Florida reef ecosystem. Impacts associated with coastal construction projects and activities conducted by contractors unaware of the presence and vulnerability of the reef could be reduced through a combination of strategies to increase awareness and by refining some practices to better protect coral reef habitats.

Hawaii

In Hawaii, the *Climate Change and Marine Disease Local Action Strategy* illustrates how the LAS process can provide a mechanism to apply adaptive management among and between various regions and jurisdictions. *Hawaii's Climate Change and Marine Disease Local Action Strategy*, in part, is a good example of how a jurisdiction has taken existing programs and activities that have proven successful elsewhere and adapted them to meet the specific needs and to accommodate the stakeholder community in Hawaii. In designing this LAS, Hawaii has adopted and adapted monitoring programs and protocols that have proven successful in both Australia and Florida. In addition, Hawaii has taken advantage of an existing network of coral disease experts, the Coral Disease and Health Consortium, to strengthen and enhance their existing capacity for coral disease research, training, and management activities. (Report citations can be found in the reference section.)

As these two examples show, the LAS process provides the USCRTF members with a mechanism to translate national level goals into action for locally driven priority needs. Additionally, at the local level there is opportunity for flexibility and adaptive management schemes in the design and implementation of the LAS.

National Priorities Implemented Locally

While the USCRTF has taken advantage of its unique membership working directly with jurisdictions to

identify and address their priority coral reef conservation issues, the USCRTF continues to coordinate action at a national level. The USCRTF provides a forum for Federal agency members to explore how their diverse mandates, authorities, and programs can be used in concert to reach common conservation goals.

One such example is a U.S. Department of Agriculture (USDA) and NOAA collaborative partnership with Puerto Rico in the Jobos Bay National Estuarine Research Reserve. USDA's Conservation Effects Assessment Project is an effort to quantify environmental effects and benefits of conservation practices on upland agricultural lands. NOAA contributes the scientific research and monitoring data of the near-coastal waters to help make the connections between land-based conservation practices, near-shore water quality parameters, and sediment chemistry within the Bay. This is the first such project in the tropics and is an initial effort to link USDA land conservation practices with NOAA coral ecosystem monitoring activities to determine ecological impacts from land-based sources of pollution.

The USCRTF aims to promote more of these national programmatic partnerships effectively directed towards on-the-ground conservation actions and solutions.

Challenges and Weaknesses

While the USCRTF provides a forum for collaboration across Federal and local agencies, the USCRTF has faced a number of significant challenges in its attempts to increase coordinated action to conserve valuable coral reef ecosystems and the communities that depend on them. At the core, the Executive Order that established the USCRTF is not technically binding in any way, and therefore, provides no explicit authority for the USCRTF as a body. In addition, the USCRTF has no budget or independent source of funding to help promote and facilitate collective and coordinated action but rather is dependent upon individual agency budgets that can be applied to coral reef related activities. The USCRTF serves as an effective planning and coordination body at some levels; however, one of the greatest challenges has been efforts to identify conservation goals and targets, and the establishment of performance metrics at national to local levels to track progress towards the *National Action Plan* goals. The lack of such conservation targets impedes the ability to assess the overall impact the USCRTF or member actions have for conserving coral reef ecosystems.

These fundamental limitations are compounded by the challenges inherent in working cooperatively across many diverse partner mandates, authorities, and interests at the national and local level. For example, the initial process to develop LAS was not necessarily an easy or smooth transition among members to restructure their organizational framework to better link national goals to local action. This, combined with varying levels of capacity to develop and implement LAS has resulted in differing degrees of success across jurisdictions and throughout the life cycle of LAS projects.

Finally, at the National level, the USCRTF and its members are not taking full advantage of the Federal authorities and the potential role they could play in reducing impacts on reefs from threats directly or indirectly impacting coral reef systems. Action also needs to be stepped up across the USCRTF to better implement the Executive Order charge for Federal members "to ensure actions they authorize, fund, or carry out will not degrade the conditions of such ecosystems."

Conclusion & Discussion

Partnership for strategic and collaborative action

The USCRTF has created a range of effective partnerships and in turn, developed much needed capacity at the national and local level. Through the USCRTF, Federal agencies are directed to work together to address, in a collective and strategic way, the threats to coral reef ecosystems and to lead, coordinate, and strengthen U.S. Government actions to conserve coral reef ecosystems. To fulfill this mission, the USCRTF developed national strategies, targeted initiatives, and new partnerships to strengthen stewardship of the coral reef ecosystems in the United States and around the world.

In the ten years since its inception, the USCRTF has taken a variety of actions to reduce key threats and adverse impacts to coral reef ecosystems. It has led the development of national and local strategies to conserve coral reefs, increased collaboration among federal agencies and jurisdictions in coral reef regions, and helped its members launch new actions to protect and manage reef ecosystems. In particular, the real and tangible value of the USCRTF is through its efforts to create a forum for and to build upon the following:

- Foster Partnership
- Strengthen Coordination
- Increase Financial and Technical Resources
- Promote Efficiency
- Improve Effectiveness

However, despite these efforts, many reefs continue to be degraded or destroyed by unsustainable fishing, destructive fishing practices, land-based pollution, and coastal development, among other natural and human-induced impacts. In addition, climate change is having a variety of impacts on coral reef ecosystems, including increasing acidity of our oceans and the loss of corals from bleaching and disease linked to increased sea surface temperatures. Continued efforts for coral reef conservation are dependent upon a host of partners and require a multi-faceted approach. It is essential that the scientific understanding, tools and political will at all government levels exists to take effective action to address the threats these reef systems face. The USCRTF must seek to better utilize individual member authorities, programs, and expertise at the national and local level to respond more effectively to those threats that the USCRTF has the capacity to address.

The USCRTF continues to build on this strong foundation to develop and advance new and innovative opportunities for collaboration among Federal agencies and coral reef jurisdictions. Urgent, coordinated action and a recognition that greater authority is needed to stem further decline of these valuable coral reef ecosystems.

Finding the right fit for ecosystem-based management in the Philippines

R. Eisma-Osorio[1]

1) Coastal Conservation and Education Foundation, Inc., 302 PDI Condominium, Banilad, Cebu City 6000, Philippines

Abstract. Spatial scales for ecological marine protected area networks do not necessarily fit into existing governance frameworks in the Philippines. The Philippines adopts a highly decentralized approach to coastal management including marine protected area (MPA) management. Each local government authority exercises management powers and responsibilities over their coastal zone which is measured from the shoreline to 15-km seaward of municipal waters. The local government initiatives have resulted in the establishment of over 300 MPAs in Central Philippines to improve marine habitats and enhance fishery resources, with only 20-30% of MPAs effectively managed with sustainable fishery benefits. With the increasing number of MPAs, the need for joint MPA management efforts in order to increase management effectiveness as well as protect areas beyond MPA boundaries has arisen. Thus, a definitive governance structure has been sought within the fisheries ecosystem scale following the ecosystem-based management approach. This paper will present the management strategies, outcomes and lessons of the Local Governance for Coastal Management Project for the Management of Coral Reefs and Fisheries in the Philippines since January 2002. The project has been working towards scaling-up the geographic scope to achieve the desired results in fisheries ecosystem management by expanding from a municipal up to a much broader collaboration at the inter-municipal, provincial and regional scale. It focuses on activities that address the needs in institution building and strengthening, fisheries management, habitat management, foreshore management, and coastal law enforcement. Creating marine protected area networks at adequate ecological scales do not fit into existing single municipal waters governance frameworks in the Philippines. Achieving ecosystem-based fisheries management will require developing new governance arrangements across municipalities and the cooperation of municipal leaders who recognize the need to manage fisheries at ecosystem scales.

Key words: ecosystem, governance, scaling-up, collaboration, management

Introduction

The Philippines adopts a decentralized approach to coastal management, which includes establishment and management of marine protected areas (MPAs). Each local or municipal government authority exercises management powers and possesses responsibilities over their coastal zone measured from the shoreline to 15-km seaward of municipal waters.

To improve marine habitats and enhance fishery resources, the municipal governments in Central Philippines have now established over 300 MPAs. Unfortunately, only 20-30% of these MPAs are effectively managed with sustainable fishery benefits (White et al. 2006). With the increasing number of MPAs, the need for joint management efforts in order to increase MPA management effectiveness at an ecological scale has arisen. There is likewise a need to protect areas beyond MPA boundaries in order to optimize benefits from these no-take zone areas.

At the same time, there is an increasing recognition of the need to manage no-take or restricted take MPAs at an ecosystem scale, following the ecosystem-based management approach. But the decentralized governance structure has posed a seemingly insurmountable challenge towards effective management of these MPAs.

Materials and Methods

This paper draws from the management strategies, outcomes and lessons of the Local Governance for Coastal Management Project for the Management of Coral Reefs and Fisheries in Central Philippines supported by the David and Lucile Packard Foundation since January 2002. It details the evolution of integrated coastal management practices in the municipal waters of a single municipality into an expanded management and governance arrangement by taking into consideration a fisheries

ecosystem covering multiple municipalities in Central Visayas, Philippines (Fig.1). In particular, the paper intends to show initial steps towards EBM starting from a municipal level MPAs with emphasis at scaling up to MPA networks with a facilitating inter-municipal governance structure. It captures the process of how the EBM strategy was used to address common issues that needed to be commonly addressed by a group of municipalities. Information obtained for this paper stemmed mainly from internal project reports and biophysical monitoring results of the project.

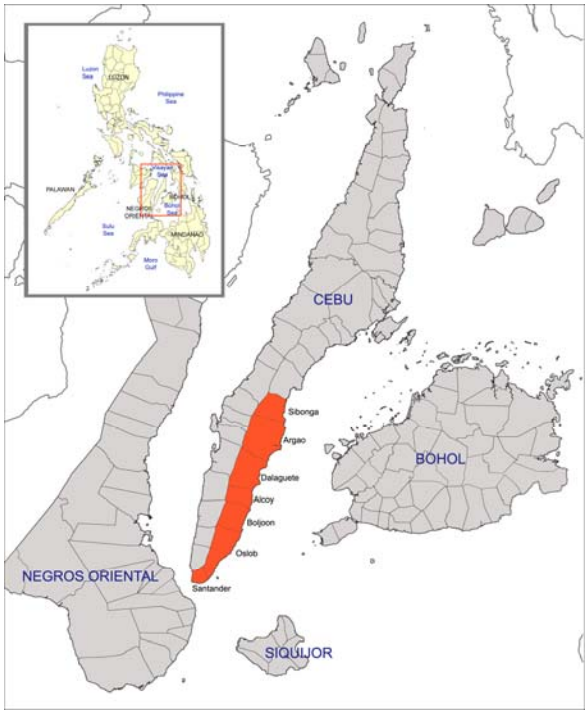

Figure 1. Southeastern Cebu municipalities, Central Visayas, Philippines

The Ecosystem Boundaries

The Philippines is considered to have coastal management programs functioning in 1/6 of 18,000 km of shoreline (White et al. 2004) with an emphasis on establishment of marine protected areas (MPAs) and fisheries management. The municipalities achieved most of the key coastal resource management (CRM) benchmarks such as:

- Adoption and implementation of a multi-year CRM plan providing overall framework and direction in managing the coastal resources of the municipality/city;
- Coastal environmental profile developed through secondary data compilation and baseline assessment (e.g., participatory coastal resource assessment, rapid assessment, scientific surveys) of coastal resources and socioeconomic and environmental conditions;
- Annual programming and budget to sustain local CRM plans and programs, with trained staff and operating municipal/city CRM unit or office; and
- CRM-related organizations in the form of People's Organizations, Fisheries and Aquatic Resource Management Councils, or Technical Working Groups, formed and active.
- Shoreline/foreshore management measures planned

The municipalities have likewise initiated various CRM best practices, such as municipal water delineation, MPAs, mangrove management, fisheries management, local legislation identified in the CRM plan, coastal law enforcement, coastal environment-friendly enterprise development, revenue generation, and multi-institutional collaboration for CRM. These benchmarks/series of tools are considered the minimum that a municipality should implement if it adopts coastal and fisheries management as a basic service (DENR 2003).

Thus far, more than 1,000 community-based MPAs (Arceo et al. 2007) have been established all over the country.

The Study Area

In Central Philippines, particularly Southeast Cebu, eight coastal municipalities traverse an irregular coastline of about 118 km. The area is bounded on the east by the Cebu/Bohol Strait, a body of water separating the islands of Cebu and Bohol with more than 158.6 km^2 of coral reef ecosystem. The eight coastal municipalities have a >125,000 ha of total combined area of municipal waters.

Based on a comprehensive study on the fisheries profile by Green et al. (2003) seven fisheries ecosystems in Central Visayas were identified. These ecosystems were considered as discrete ecosystems wherein within each ecosystem are multitudes of habitats, such as mangrove forests, coral reefs, seagrass, mudflats, sandy beaches and others. These habitats are the main feeding grounds, nursery areas and spawning grounds of coastal-dwelling marine aquatic organisms. These ecosystems, also known as the Visayan Seas, are also considered as one of the marine priority conservation areas in the Philippines. Over 400 MPAs have been established so far in the 4 Provinces of Central Visayas (UPMSI Database 2007) to improve marine habitats and enhance fishery resources, with only 20-30% of MPAs effectively managed with sustainable fishery benefits.

The Cebu/Bohol Strait fisheries ecosystem was identified as one of these fisheries ecosystem in the

Central Visayas region. It was found to contain 1,500 identified aquatic and marine species moving around areas of up to 5,000 km^2. It also supports over 5,500 small-scale fishers, however, there are existing massive threats to coral reefs and associated habitats, foremost of which is the over-exploitation of coastal and marine resources.

Despite all these obstacles, the Southeast Cebu municipalities have established 22 MPAs, thus far, in the Cebu/Bohol Strait in about 300 ha. consisting of about .24% of the total combined municipal waters.

Rationale for the EBM approach and scaling-up of MPAs

With the increasing number of MPAs established in Southeast Cebu, the need for joint MPA management efforts between the eight municipalities in order to increase management effectiveness as well as to protect areas beyond MPA boundaries has arisen. These municipalities are primarily mandated to manage their respective municipal waters under Philippine fisheries laws. Sweeping and comprehensive powers were granted through local devolution for direct management of municipal waters, hence, these powers by themselves provide inherent challenges in terms of expanded management required within ecosystem boundaries. Joint management efforts of a single ecosystem go beyond MPA and/or municipal boundaries to include multiple municipal jurisdictions.

In previous years, the said municipalities have begun implementing their CRM plans, mostly focusing on establishment of MPAs and have likewise achieved key CRM benchmarks as indicated above. It was, thus, well-placed for "scaling up" to MPA networks as ecosystem based management commonly involves "scaling-up" from design of individual protected areas to planning for MPA networks.

In Search of a definitive EBM structure

Municipal waters in the Philippines are primarily managed by municipalities. However, one of the most frequently cited reasons for weak implementation of coastal management programs through subordinate units of government at provincial and local levels is the lack of resources and capacity to carry out the required tasks. In fact, most coastal municipalities/ cities have limited financial and technical resources

To overcome these obstacles as well as to address the need for municipalities to 'scale-up' resource management and governance at a broader geographic scale, the eight coastal municipalities decided to sign a Memorandum of Agreement and create the Southeast Cebu Coastal Resource Management Council in 2005. This conforms to the current legal/institutional regime in the Philippines. Philippine laws recommend integrated management of contiguous fisheries areas.

Specifically, the State policy espoused by the Philippine Constitution provides that *"Local government units may group themselves, consolidate or coordinate their efforts, services, and resources for purposes commonly beneficial to them."* The Local Government Code of 1992 or Republic Act 7160 likewise grants genuine and meaningful local autonomy to municipalities whereby more powers, authorities and responsibilities are granted to municipalities in the management of their municipal waters. This includes the mandate for innovative and collaborative partnerships through appropriate ordinances in order to contribute funds, real estate, equipment and other kinds of property and appoint or assign personnel as may be agreed upon by the participating municipalities through a Memorandum of Agreement. In 1998, the Philippine Fisheries Code (Republic Act 8550) adopted the concept of integrated coastal management for the management of fishery and aquatic resources by municipalities and/or cities. It declares that it is the policy of the State to *"manage fishery and aquatic resources, in a manner consistent with the concept of an integrated coastal area management in specific natural fishery management areas, appropriately supported by research, technical services and guidance provided by the State."*

In the same manner, the Fisheries Code maintains that municipalities which share or border common water resources may group themselves and coordinate with each other to achieve the objectives of integrated fishery resource management in contiguous fishery resources such as bays, lakes and gulfs which straddle several municipalities.

It is clear that there are existing legal precedents that mandate municipalities to collaborate and build on existing and on-going municipal initiatives for coordinated coastal and fisheries management. Thus, MPAs are now increasingly managed collectively thru a "cluster" of municipal governments. In Southeast Cebu, there are now 22 MPAs (ave. of 13.6 ha) in about 300 ha with no-take areas covering .24% of total combined municipal waters. And these are currently managed as a MPA network by the cluster of eight municipalities.

To ensure collaboration and collective responsibility, a coordinating body for all identified programs of the eight municipalities was formed through the Southeast Cebu Coastal Resource Management Council. It is composed of Mayors and Vice-Mayors of eight municipalities that functions as a policy-making and supervising body. A complete set of officers led by a Chairman is elected among the Vice-Mayors of the municipalities who shall hold

their positions for three years co-terminus to their term of office as elected officials.

To assist the Council, a management committee and a secretariat, composed mostly of technical staff from each municipality, was organized. In addition, a technical and legal advisory group coming from government agencies such as the Department of Environment and Natural Resources, Bureau of Fisheries and Aquatic Resources, and Philippine National Police, as well as NGOs such as the Environmental Legal Assistance Center and the CCEF, provides specialized support to the Council. The Council often calls on any of these government agencies and/or non-government organizations for technical inputs, legal advice, logistical support, and other forms of technical assistance. The management committee headed by an Executive Director administers the day-to-day activities of the Council while the secretariat serves as the record keeper and financial manager. Both the management committee and secretariat have provided an effective coordination and feedback mechanism to respective municipalities.

Significant Socio-Institutional and Bio-physical Outcomes

The Council, although still young and evolving, is now a venue for the discussion and resolution of important issues and activities. It focuses on activities that address the needs in institutional building and strengthening, fisheries management, habitat management, foreshore management, and coastal law enforcement.

Through the Council meetings, issues such as the banning of compressor fishing; protection of critical habitats from foreshore development; the reduction of fishing effort through fisherfolk, fishing gears and boat registration, regulating *pa-aling* (modified *muro-ami*) and banning *sagiwsiw* (modified drift gill net) fishing, and strict enforcement against intrusion of commercial fishing into municipal waters. The Council has likewise considered other concerns such as the oil seismic survey along Cebu Strait; regulating municipal tourism activities; and creating social networks among MPA managers. In effect, the multi-municipality MPA network has developed into a strong institution capable of effective coordination and management actions.

It has also successfully opened a venue for the provincial government to downstream support for coastal management at the inter-municipal levels. Some contextual issues such as weak formal institutions and three-year terms of municipal mayors (Christie, et al 2007) have been avoided as well. Periodic political and leadership changes have not affected coastal management programs with the smooth transition, stability, and continuity of the Council and its functional committees.

Through the Council, municipal coastal management initiatives in the eight municipalities have been re-energized. MPAs are now effectively managed, with initial results from biophysical monitoring suggesting an increasing trend in percentage of live hard coral cover recorded inside MPAs (Figure 2) and fish abundance of commercially valuable fishes (target fishes) (Fig.3).

Biophysical reef monitoring of MPAs involves a participatory method in estimating fish populations and substrate composition with competent local community members. Surveys are conducted in the shallow reef (3-4m depth) and deeper portion of the reef (7-9m depth) both inside and outside the MPA boundaries for comparative changes due to protection.

The results of the monitoring surveys have been used as inputs for MPA management decision-making at the municipal government and municipal cluster levels.

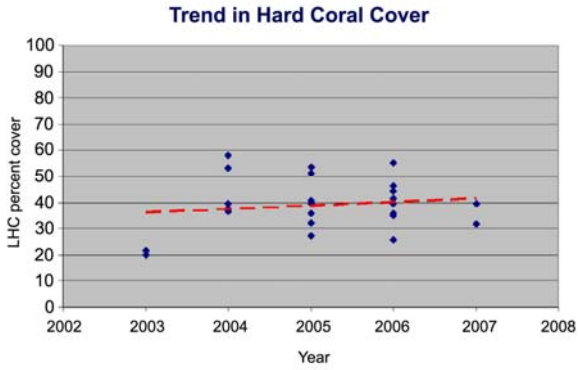

Figure 2. Trend in Hard Coral Cover of SE Cebu MPAs

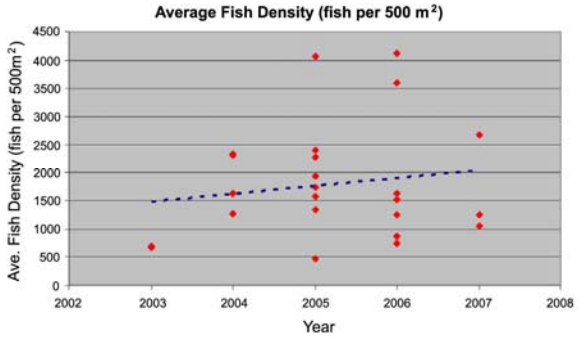

Figure 3. Trend in Average Fish Density of SE Cebu MPAs.

With improvements in reef status, management effectiveness of reef managers has likewise increased by at least one degree using the MPA Rating and Database System developed by the Coastal Conservation and Education Foundation, Inc. It is a

point-based rating system that is designed to aid MPA managers in evaluating their performance in terms of management, implementation, and enforcement (White et al. 2006). The extent of management is measured according to: enforcement, education, capacity development, biophysical monitoring, and sustainable financing, with Level I (MPA is initiated) up to Level V (MPA is institutionalized.

There has also been a significant reduction of threats to the coastal habitats through improved efficiency and cost-effectiveness of joint management actions (e.g., law enforcement). Municipal seaborne and coastal law enforcers (MUSCLE) have been formally organized with an institutionalized incentive scheme. To supplement the monitoring, control and surveillance of the MUSCLE, joint seaborne operations have also been supported by the Council. Currently, over 30 commercial fishing violators have been apprehended during joint law enforcement operations since April 2005. With the success of the SE Cebu cluster, other municipalities in the Province are now doing corresponding processes of clustering into inter-municipal governance arrangements.

Lessons: What will determine the right fit?

It is important to adjust natural resource governance regimes to the size and nature of the ecosystem, and to work within the range of administrative arrangements allowable to find the right fit. The administrative boundaries that fit the demands of EBM will vary according to the local context. In the Philippines, the right ecosystem fit depends on the manageability and consensus among leaders of municipal government units. It cannot be a "one ecosystem size for all" approach in EBM in the Philippines. What size is appropriate will depend on the nature of the resource(s) to be managed and the drivers that determine the status of the resource on the one hand, and the mutual decisions of the leaders to work together to manage these environmental, social and economic drivers that are affecting the system—in this case the fisheries ecosystem.

The extent of the Cebu/Bohol Strait fisheries ecosystem is limited to the municipal water boundaries of 8 municipalities. A separate management structure was organized by these municipalities in order to provide a platform for ecosystem-based management of this fisheries ecosystem. This inter-municipal management council – known as the Southeast Cebu Coastal Resource Management Council – has become the commonly-agreed upon and committed governing body for "scaling-up" to EBM of the network of MPAs found therein, and hopefully the marine space in-between.

Conclusion

Spatial scales for ecological marine protected area networks do not fit into existing single municipal waters governance framework in the Philippines. Thus, to be effective in managing ecosystem boundaries, there is a need to expand and create a separate governing authority to govern multiple municipal governments. With ecosystem values foremost in the management considerations, governance regimes in the Philippines allows for such expansion or "scaling up." Inevitably, ecosystem boundaries are usually set using a balance of ecological functions and appropriate governance considerations.

Acknowledgment

The author would like to express her gratitude to Dr. Alan T. White and Dr. Patrick Christie who provided helpful insights to some portions of this paper. This work would not have been possible without the support of the Coastal Conservation and Education Foundation (CCEF), Inc. with financial assistance from the David and Lucile Packard Foundation. Finally, I would like to express my sincerest thanks to the hardworking men and women of the CCEF, especially Rizaller Amolo, Sheryll Tesch and Aileen Maypa.

Post hurricane dynamics and status of coral reefs St. Croix, US Virgin Islands

D.P. Fisco

400 Hillside Ave. Mill Valley, Ca 94941 DanaFisco@gmail.com

Abstract. To protect the vitality of Caribbean reefs, it is important to understand the physical and biological factors affecting the status of corals. Hurricane Hugo caused extensive damage on the island of St. Croix, US Virgin Islands in 1989. Underwater transects were set up on Tague forereef in 1989 and 2007 to study the coral species. The data show that there was an increase in both overall live coral species richness and total live coral present on Tague forereef eighteen years after Hurricane Hugo. These data were also compared with those collected on the south forereef of Buck Island Reef National Monument to assess the state of a protected reef after the hurricane. No significant difference was found between the percentage of live coral cover on Buck Island south forereef and Tague forereef in 2007. This suggests that marine protected areas alone cannot prevent the degradation of Caribbean coral reefs, and more effort must be placed on large-scale prevention of tidally transported coral-damaging factors.

Key Words: Caribbean, Hurricane, Marine Protected Area

Introduction

Hurricanes are acute physical factors that have immediate effects on the dynamics of coral reefs (Bythell et al. 1993b; WS1 2008). The intensity of hurricanes is escalating (Lugo 2000; Aronson and Precht 2006; WS1 2008)—under doubled CO_2 conditions they are estimated to be 10-20% stronger (Kleypas et al. 2001). Strong currents, large tidal ranges and transported debris can knock over large branches, roll heads of coral and smother live coral polyps (Bythell et al. 2000). According to the Intermediate Disturbance Hypothesis (Connell 1978) hurricanes can have positive effects—when of intermediate frequency—on coral reefs by clearing suitable substrata for new coral recruits that might have otherwise been outcompeted for space (Bythell et al. 2000). However, the analysis of the long-term consequences of major physical effects of storms is complicated by chronic biological factors (Bythell et al. 1993a; Bythell et al. 1993b; Bythell et al. 2000; Humann and DeLoach 2002; Aronson et al. 2005; WS1 2008).

On September 17-18, 1989, Hurricane Hugo raged over St. Croix for more than 12 hours (Hubbard et al. 1991; Bythell et al. 1993a). The category 4 storm was the first hurricane since 1928 to directly hit the island of St. Croix (Hubbard et al. 1991; Bythell et al. 1993a; Bythell et al. 2000). The near-shore reefs on St. Croix endured large waves, estimated at 6-7 m in height on Tague Reef, which caused erosion and increased sediment transfer (Hubbard et al. 1991). This study aims to analyze the effects of a major disturbance on the reefs of St. Croix.

Caribbean coral reefs have undergone a phase shift from coral to algal dominance since the late 1970s (Aronson and Precht 1997; Graham et al. 2006). These shifts have primarily been attributed to over-fishing as well as the Caribbean-wide disease related die-off of the echinoid, *Diadema antillarum* in 1983-1984 (Humann and DeLoach 2002; Aronson and Precht 2006; Mumby et al. 2006). Without the presence of the dominant algal grazer, *D. antillarum,* on Caribbean reefs, herbivorous fish such as parrotfish and surgeonfish, have become the dominant macroalgal grazers. Most marine protected areas (MPAs), such as Buck Island Reef National Monument (BIRNM), are primarily established to protect over-fished populations of tropical fish (Hughes et al. 2002). By restoring the abundance of herbivorous fish, MPAs are proposed to protect corals by increasing the grazing pressures on the macroalgal communities thus allowing colonization space for coral recruits (see Aronson and Precht 2006 for a review of related studies). Comparison of data from protected and unprotected reef sites on St. Croix suggests that the protection of a reef alone does not allow for a higher colonization of hard corals.

Materials and Methods

St. Croix Island is located in the Caribbean Sea and is a part of the USVI (Fig. 1A). Tague forereef

protects the northeast shore of the mainland in an east-west orientation.

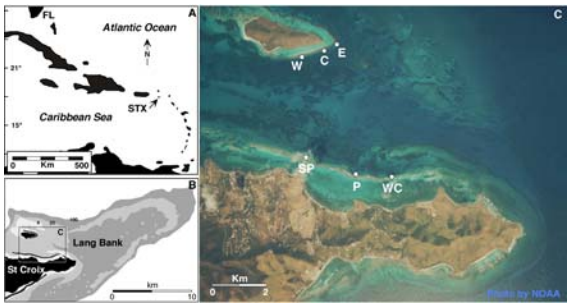

Figure 1: Map showing study localities: A) Island of St. Croix . B) Buck Island Reef National Monument and Tague Reef. C) Three study sites on Tague Reef and Buck Island south forereef. Tague Reef localities are Whaler Cut (WC); Platform (P); and Solar Panel (SP). Sites on Buck Island south forereef are West (W), Center (C), and East (E).

BIRNM is located 2.5 km off the northeast coast of St. Croix. Established as a National Monument in 1961, the continuous barrier reef forms an arc on the north and south-east side and protects the island from a primarily easterly wave action (Hubbard 1991). The southern forereef (Fig. 1C) has been monitored since 1988. The south forereef is usually protected from 'near-miss' hurricanes due to its proximity to the mainland of St. Croix, but when Hurricane Hugo passed directly over the island, BIRNM south forereef was hit harder than any other on St. Croix (Hubbard et al. 1991; Bythell et al. 1993a).

In the winter of 1989-1990, about three months after Hurricane Hugo struck St. Croix, data were collected at three locations on Tague forereef (Fig 1C) (Hubbard 1991; Hubbard et al. 1991; Hubbard pers. comm. 2007).

New data collections during the summer of 2007 were performed at the same three locations on Tague forereef—located by GPS—and at an additional three locations on Buck Island south forereef (Fig. 1C) (Fisco 2008). A meter tape was used to measure every contour and type of substrate—live coral, dead coral, coral rubble, sand and pavement—along the horizontal chain transects. The species of live coral, dead coral and coral rubble was recorded.

An assessment of the total live coral of each species was performed between 1989 and 2007, and differences in species richness and dominant species were noted. The species composition and total percent live coral cover of the substrate were compared between Buck Island south forereef and Tague forereef to assess the differences between a protected reef and one that is not.

Results

The results of this research are of two kinds. The first set of data analyzes the trends in species richness at the three Tague forereef locations between 1989 and 2007. This includes an analysis of low relief vs. high relief species. Low relief species are smaller species of coral which form encrusting colonies, up to 0.6 m in diameter, and therefore are not significant reef builders (Humann and DeLoach 2002). High relief species are those which grow to be as big as 4 m in diameter and add significantly to the structure of the reef (Humann and DeLoach 2002). The second set of data shows trends in total live coral cover between 1989 and 2007 at the three Tague forereef locations as well as a comparison of live coral between Tague forereef and Buck Island south forereef.

Trends in Species Richness

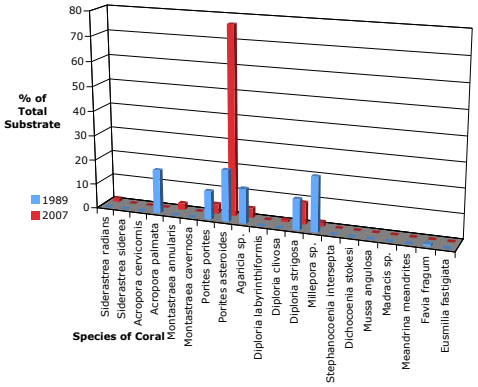

Figure 2: Comparison graph showing the percentage of total live coral of each species between 1989 and 2007 at 3 m depth, averaged between the three locations: Solar Panel, Whaler Cut and Platform.

The 3 m depth transects did not display a large species number influx in the eighteen years between Hurricane Hugo and the 2007 survey. On average, only one more species was found at the 3 m depth (Fig. 2). *Favia fragum* died out completely, as did *Acropora palmata*. *Siderastrea radians, Montastraea annularis,* and *Diploria clivosa* are three smaller, low-relief coral species that were not represented in the 3 m assemblages in 1989 but were present on the reef in 2007.

With a total of four species, the number of species of corals at 6 m was relatively low in 1989, this number more than doubled by 2007 with thirteen species present in the three locations (Fig. 3). In both 1989 and 2007, *Porites porites* represents the highest proportion of live coral present at 6 m on Tague forereef. In 2007, the low relief species *Agaricia* sp. (22.5%), *Siderastrea radians* (15.7%) and *P. asteroides* (15.4%) were

relatively dominant. All of the species present at the 6 m depths are considered low relief, non-framework building corals. Although no species had died out, eight new species had colonized the 6 m depth of Tague forereef by 2007.

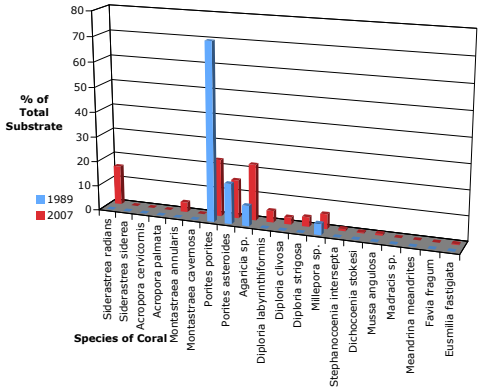

Figure 3: Comparison graph showing the percentage of total live coral of each species between 1989 and 2007 at 6 m depth, averaged between the three locations: Solar Panel, Whaler Cut and Platform.

The 9 m depth also showed an overall trend of increasing species richness. While only four species were recorded in 1989, the 9 m depth experienced a threefold jump in number of species to twelve species in 2007 (Fig. 4). In one of the transects, Whaler Cut 6 m, 100% of the live coral assemblage was composed of *M. annularis* in 1989. In 2007, at this same transect, the *M. annularis* population accounted for only 8.3%, while *Porites porites*, a smaller branching coral, dominated the assemblage with 32.2% of the live coral cover.

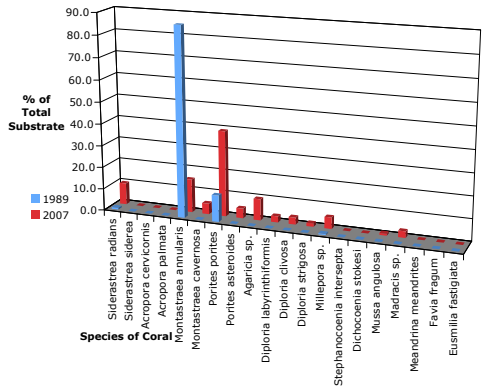

Figure 4: Comparison graph showing the percentage of total live coral of each species between 1989 and 2007 at 9 m depth, averaged between the three locations: Solar Panel, Whaler Cut and Platform

Trends in Live Coral Cover

Table 1: Total percent of the reef composed of live coral cover in 1989 and 2007.

Year	Total % Live Coral
1989	10.5%
2007	12.3%

On average, the total amount of live coral present on Tague forereef increased by 2.3% in the eighteen years after Hurricane Hugo (Table 1). Although an increase was observed, the percent of live coral present on the reefs in both studies was very low.

Table 2: Percent live coral cover of total substrate by location and depth on Tague forereef. Depths that experienced an increase in coral cover over the 18-year period are underlined.

Depth	Year	Location		
		Solar Panel	Whaler Cut	Platform
3 m	1989	6.6%	2.6%	3.2%
	2007	*22.3%*	*6.2%*	*7.7%*
6 m	1989	9.0%	26.8%	10.9%
	2007	*16.1%*	9.0%	7.2%
9 m	1989	0.0%	18.4%	17.3%
	2007	*1.9%*	7.6%	9.1%
Average	1989	5.2%	15.9%	10.5%
	2007	*13.4%*	7.6%	8.0%

Though there was a general trend towards increasing species richness in all but one transect between 1989 and 2007 (Fig. 2-Fig. 4), the Whaler Cut and Platform transects showed a decrease in the average percent of live coral cover (Table 2). The Whaler Cut 6 m transect showed the greatest change in coral cover—a 16.8% *decrease* in live coral cover occurred between 1989 and 2007. All of the depths at the Solar Panel transect showed a relatively large increase (an average increase of 8.2%) in live coral.

Table 3: Average total live coral measured between Buck Island south forereef and Tague forereef in 2007. The percent of the substrate covered by live coral cover is listed in parentheses.

	Average total live coral measured (m)	
Depth	**Buck Island**	**Tague Reef**
3 m	2.15 (15.7%)	1.60 (14.2%)
6 m	1.71 (10.9%)	1.64 (12.9%)
9 m	1.67 (10.4%)	1.21 (9.8%)
Average	1.84 (12.3%)	1.48 (12.3%)

In 2007, there is almost no difference (0.36 m) between the total amount of live coral present on Tague forereef and Buck Island south forereef. The average percent of the substrate covered by live

coral is the same on Buck Island National Monument and Tague forereef (Table 3).

The coral species present at each reef are different but on the whole, the reefs of St. Croix and Buck Island south forereef contain relatively small, non-framework building corals.

Discussion

Because of the close interaction between humans and the natural environment, it is important to understand how ecosystems react and respond to major disturbances such as hurricanes so that we can try to adjust and plan accordingly.

In a paper detailing the effects of hurricanes in the Caribbean, Lugo (2000) discusses the impacts on terrestrial vegetation. The pattern witnessed by Lugo (2000) closely resembles that of the Intermediate Disturbance Theory proposed by Connell (1978). At first, in terrestrial environments, there is massive mortality of vegetation over a short time period (Lugo 2000; Done, 1999). This mass mortality is followed by a delayed pattern of tree mortality (Lugo 2000). The final step is a high turnover of terrestrial species.

The reefs of St. Croix post-Hurricane Hugo are a good example of Lugo (2000) and Connell (1978)'s models. At first, Bythell et al. (1993a) recorded a loss of 40-46% of the pre-hurricane live coral cover on Buck Island south forereef. Hubbard et al. (1991) also reported near total destruction of the south facing reefs on Buck Island. Next, Bythell et al. (2000) found that the coral abundance on the reefs of St. Croix remained in the immediate post-hurricane condition for two to three years before returning to approximate pre-hurricane levels by June 1991 (Bythell et al. 1993a).

Lugo's last observation is clearly demonstrated, as there were only two locations at which the dominant coral species did not change in the eighteen years between the two studies on Tague forereef, and species richness increased in all but one transect. Bythell et al. (2000) found that the recruitment of coral species on the south side of BIRNM was strong following Hurricane Hugo. The massive sediment transfer, reported by Hubbard et al. (1991) on the reefs of St. Croix could allow for settlement 'colonization gaps' in which new recruits with better regeneration strategies could settle and flourish. Bythell et al. (2000) found that the area most severely impacted by hurricane disturbance demonstrated the greatest increase in species richness of all the sites studied due to high recruitment of uncommon species into the newly cleared niches. These high recruitment rates are essential to sustaining the ability of the reefs to re-establish complex communities in the wake of hurricane damage (Bythell at al. 2000).

An apparent shift has occurred from high relief, framework building corals to smaller, low relief, non-framework building corals, soft corals and macroalgae (Aronson and Precht 1997; Done 1999; Aronson and Precht 2006). Population modeling suggests that an increase in the frequency and/or the intensity of disturbances should tend to skew size frequency distributions towards smaller size classes of organisms (Done 1999). These population models could help explain why there was a large increase in dominance of small, low relief coral populations on the reefs of St. Croix.

Reef building by larger corals is very important for reefs to cope with global sea level change (Grigg 1998; Kleypas et al. 2001). Globally, there are many documented cases where reefs have failed to keep up with Holocene sea-level rise and subsequently contain no live corals (Kleypas et al. 2001). The rate of reef growth in these cases was too slow to keep the corals and their algal symbionts in the photic zone. The production of calcium carbonate by larger, high relief, branching corals also provides topographical complexity, including nooks and crannies that support the vast number of reef species.

BIRNM has been nationally protected for 46 years, but no significant difference was found between the percent live coral cover on Buck Island south forereef and Tague forereef (Table 4). In a study conducted concurrently with this study, and at the same locations on Tague forereef and Buck Island south forereef, Burpee (2007, pers. comm.) found that the ban on fishing established on BIRNM has been successful in protecting the herbivorous and predatory fish populations. Overall, he found that the parrotfish on Buck Island south forereef are larger and in higher abundance than those on Tague forereef. Common sense and many scientific studies lead to the conclusion that the increase in size and number of grazers would produce a decrease in macroalgal cover and provide suitable settlement substrata for new corals (Mumby et al. 2006; see also Aronson and Precht 2006 for a review of related studies). As Table 4 shows, however, there was no significant difference between the live coral cover on Tague forereef and Buck Island south forereef.

These results reveal that local conservation efforts of MPAs are only a first step in the conservation of coral reefs (Reaser et al. 2000; Hughes et al. 2002). There are many Caribbean-wide factors, such as diseases and climate change, affecting coral reefs that cannot be prevented by eliminating fishing pressures in an MPA (Aronson

and Precht 2006). MPAs can, however, be greatly aided by better management of surrounding ecosystems and more effective, stronger international efforts to reduce global warming (Reaser et al. 2000; Hughes et al. 2002; Aronson and Precht 2006).

The extent of damage from tropical storm and the subsequent recovery of reefs are highly variable between reef sites (Bythell et al. 1993a), and we are just beginning to understand influences on coral reef community structure (Bythell et al. 1993a). The data collected in 1989 (Hubbard 2007, pers. comm.) and 2007 should help contribute to future analyses of the effects of tropical storms on the reefs of St. Croix. More frequent and regular surveys should be performed on St. Croix and Buck Island reefs to evaluate exactly how the communities adapt to large-scale disturbances.

Conclusions

Coral reef communities are dynamic and are constantly driven to change due to many biological and ecological processes, including environmental disturbances (Aronson and Precht 1997). Overall the live coral species richness has increased on Tague forereef, St. Croix, in the eighteen years since Hurricane Hugo. There were no noticeable differences in live coral cover between the protected reef on Buck Island Reef National Monument and that on the main island of St. Croix. This research shows that annual surveys of MPAs will be crucial for determining the role they can play in maintaining and/or protecting enough live coral to help re-populate reefs in the wake of ecosystem change. Without efforts to tackle global environmental issues, MPAs will not fix the problem of worldwide coral decline (Aronson and Precht, 2006).

Abstract. The U.S. Clean Water Act provides a legal framework to protect coastal biological resources such as coral reefs, mangrove forests, and seagrass meadows from the damaging effects of human activities. Even though many resources are protected under this authority, water quality standards have not been effectively applied to coral reefs. The Environmental Protection Agency is promoting biocriteria and other water quality standards through collaborative development of bioassessment procedures, indicators and monitoring strategies. To support regulatory action, bioassessment indicators must be biologically meaningful, relevant to management, responsive to human disturbance, and relatively immune to natural variability. A rapid bioassessment protocol for reef-building stony corals was developed and tested for regulatory applicability. Preliminary testing in the Florida Keys found indicators had sufficient precision and provided information relevant to coral reef management. Sensitivity to human disturbance was demonstrated in the U.S. Virgin Islands for five of eight indicators tested. Once established, monitoring programs using these indicators can provide valuable, long-term records of coral condition and regulatory compliance.

Key words: Clean Water Act, biocriteria, coral reefs, water quality standards

Introduction

Coral reefs worldwide suffer adverse effects from human activities (Lough, 2008; Knowlton and Jackson, 2008; Mora, 2008; Sandin et al. 2008). Marine Protected Areas (MPAs) are widely used in coral reef conservation to restrict fishing, diving and boating in selected areas, but cannot protect coral reefs from the many other human activities that degrade coastal zones from upstream watersheds (pollutant discharge, urban and industrial activity, agriculture) and outside MPA boundaries (dredging, dumping, fishing).

Fortunately, the Clean Water Act (CWA) provides a legal and regulatory framework to protect aquatic resources, including coral reefs, mangrove forests, wetlands and seagrasses in U.S. territorial waters. The CWA mandates that states and territories protect and restore the chemical, physical, and biological integrity of the Nation's waters (CWA Section 101 (a)). Protection extends to all territorial waters within three miles of shore, not just those within MPA boundaries, and regulatory responses to impairment can influence a range of management actions and decisions in both the coastal zone and watershed (e.g., fishery restrictions, land use allocations, building permits, effluent discharge permits). This comprehensive scope makes the CWA a powerful tool, having the potential to integrate conservation efforts across municipalities, coastal zones and landscapes. Moreover, designated waterbody uses (what to protect) and water quality standards (the level of protection) are state decisions, and therefore represent regional cultural and socioeconomic values.

The U.S. Environmental Protection Agency (EPA) is promoting development and implementation of coral reef biological criteria (biocriteria) as the most direct application of the CWA for protection and restoration of coral reefs (see Bradley et al. 2008a). The CWA requires that States and Territories define water quality standards for all waters. Water quality standards include 1) designated uses reflecting societal goals for the water body, 2) criteria to achieve the designated uses, and 3) antidegradation policies to prevent deterioration of high-quality waters. Criteria define the thresholds

(expectations) for biological, chemical, or physical indicators of resource condition and may be described in narrative or numeric terms. When biological criteria are adopted, they are legally binding—carrying both an obligation and authority to maintain the specified biological integrity. If a waterbody fails to meet the criteria, then it fails to support the designated uses and is listed as impaired in the CWA Section 303(d) report to Congress. Cause of impairment must be determined and restorative measures initiated.

Biocriteria have been broadly applied in the protection of streams, lakes, and estuaries (EPA 2002), but not coral reefs and other nearshore habitats. An important advantage of biological over physical and chemical water quality standards is that living organisms integrate the effects of multiple stressors through time, providing a reliable indicator of ecological condition (Jameson et al. 2001) rather than independent snapshots of single stressors. Biological endpoints are also transparent to stakeholders and can guide and support management decisions. Moreover, bioassessments and biological endpoints are directly responsive to the fundamental purpose of the CWA—protection of valued aquatic resources. Bioassessments incorporated into a long-term monitoring program could simultaneously provide diagnostic, management and regulatory information.

The lack of coral reef biocriteria in U.S. jurisdictions prompted EPA to initiate a collaborative program to foster development of water quality standards specifically to protect coral reef communities (Bradley et al. 2008b). A first objective was to develop bioassessment indicators and protocols suitable for regulatory application. Legally defensible monitoring programs and indicators must be scientifically sound, biologically meaningful, relevant to management, predictably responsive to human disturbance and relatively immune to natural variability. These factors are examined here for a recently introduced assessment protocol for stony corals.

The *Stony Coral Rapid Bioassessment Protocol* (RBP; Fisher 2007) was developed to capture both colony and surface area attributes of stony corals. Stony corals directly provide valuable ecosystem services (e.g., shoreline protection, community habitat) and form the infrastructure of most coral reefs. The potential of the protocol for development of biocriteria was examined in studies performed in the Florida Keys and U.S. Virgin Islands.

Material and Methods

The RBP consists of three simple underwater measurements; coral identification, coral size (height, diameter and width), and percent living tissue (Fisher 2007). Because most colonies were hemispheric, the average radius of each colony was converted to three-dimensional colony surface area (SA) using a hemispheric surrogate ($SA=2\pi r^2$). Colonies of the most abundant species in Florida and the Caribbean are hemisphere or dome-shaped, and this surrogate was found to estimate surface areas within 17% of actual (Courtney et al. 2007). Different coral species would require different geometric surrogates. Indicators (Table 1) included taxa richness, colony density and calculations of average colony surface area, total surface area (TSA), average % live tissue, live surface area (LSA), % live surface area (LSA/TSA*100) and the coefficient of variation for average colony surface area (CSA-CV) Indicators reflect both surface area (e.g., coral cover) and colony characteristics (e.g., density, size) of corals.

Two pilot studies were performed in the Florida Keys to assess the capacity of RBP indicators to detect spatial change and to evaluate the potential utility for management decisions. Studies at St. Croix, U.S. Virgin Islands further examined the potential of RBP indicators to differentiate human disturbance from natural variability. A survey was performed at stations located across a strong human disturbance gradient (industrial ship channel) on the southern shore of St. Croix. Indicators were tested for correlation with distance away from the center of the human disturbance.

Indicators of Physical and Biological Condition

Colony density: *number of colonies per m^2 sea floor*

Species (taxa) richness:*# species occurring in a defined region*

Colony surface area (CSA): *surface area (3D) of an entire colony*

Total surface area (TSA) = *Σ CSA (m^2)*

Average colony surface area (AvCSA) = *TSA/ #colonies (m^2)*

Colony size coefficient of variation (CSA-CV)=*standard deviation CSA/mean CSA*

3D Total Coral Cover (TC) = *TSA/ m^2 sea floor*

Percent Live Tissue (%LT): *percent live tissue on a coral colony*

Average Percent Live Tissue (Av%LT) = *Σ %LT/ #colonies*

[2]**Colony Live Surface Area**: *surface area (3D) of live coral tissue on an entire colony (m^2)*

Live surface area (LSA) = *Σ colony live surface areas (m^2)*

3D Live Coral Cover (LC) = *LSA/ m^2 sea floor*

Percent Live Surface Area (%LSA) = *[LSA/TSA]*100*

Table 1: Selected indicators from observations and calculations of stony corals using the Stony Coral Rapid Bioassessment Protocol (Fisher 2007).

Results

In all three studies, indicators detected differences between stations and were determined to have sufficient

precision for most monitoring programs (Fore et al. 2006). In addition, five of eight indicators tested across a human disturbance gradient at St. Croix were positively correlated with distance from the center of the disturbance zone (for example, see Fig. 1). Indicators that were responsive to human disturbance were taxon richness, AvCSA, CSA-CV, TSA and LSA. Coral density tracked distance from disturbance but the correlation was not significant. Because of small colonies with high %LT in the disturbance zone, associations of average %LT and %LSA were negative (Fisher et al. 2008).

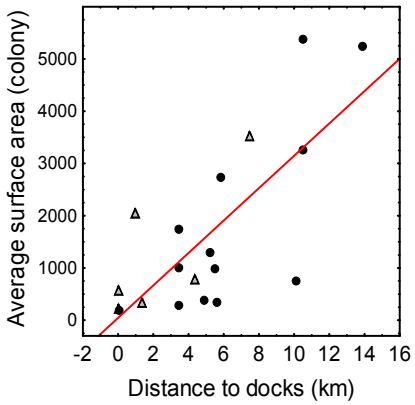

Figure 1. Relationship of colony surface area (AvCSA) with distance from commercial docks on the south side of St. Croix, USVI (from Fig. 2 of Fisher et al. 2008). This is one of five indicators that showed a predictable response from human disturbance. Triangles represent stations west of the commercial docks, circles are stations east of the docks (n = 19 stations).

In each survey, small colonies were more abundant than large colonies, but the greatest LSA was provided by mid-sized colonies (e.g., Fig. 2). Percent live tissue (%LT) declined with colony size for all species, but in the Florida Keys dropped dramatically for medium and large Elkhorn (*Acropora. palmata*) colonies (Fig. 3). Elkhorn corals provided the most reef habitat (TSA) at the Florida Keys stations, but exhibited the poorest health (LSA/TSA) relative to other species (Fig. 4). This condition was most conspicuous at a single reef, Sand Key, where numerous large *A. palmata* were devoid of live tissue (data not shown). Population structure (colony size-frequency) varied across regions for different species (Fore et al. 2006), and this was particularly evident for species at St. Croix where strong recruitment (abundant small colonies) was found at some locations and not at others (e.g., Fig. 5).

Discussion

Indicators generated by the *Stony Coral Rapid Bioassessment Protocol* (RBP) should be considered further as potential metrics in a biocriteria program. The procedures are straight-forward, inexpensive and easily measured by coral reef biologists; the indicators demonstrated sufficient statistical power to monitor for trend and detected a consistent and logical response to human disturbance over natural variability. Further, the indicators are biologically meaningful, easily interpreted by non-scientists and provide information relevant to resource management.

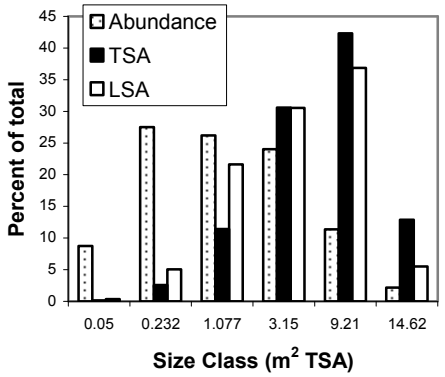

Figure 2. Relative size-class distribution of abundance (stippled bar), total surface area (TSA; dark bar) and live surface area (LSA; white bar) for *Acropora palmata* found at stations in the Florida Keys.

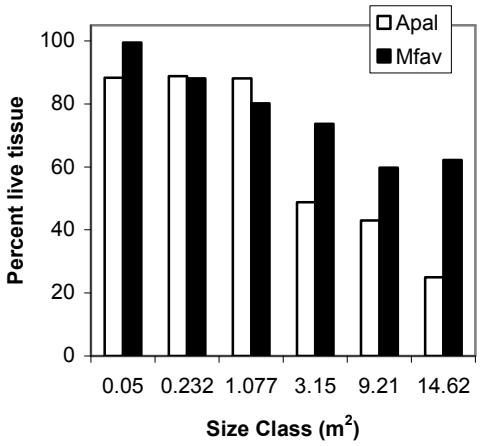

Figure 3. Comparison of the proportion of live tissue on *Montastraea faveolata* (Mfav) colonies and *Acropora palmata* (Apal) colonies relative to the size of the colonies. Large *A. palmata* had lower %LT than large *M. faveolata*.

A significant requirement for a regulatory bioindicator is predictable responses to human disturbance. It is expected that corals respond to chronically poor environmental conditions with decreasing taxon richness, size and health. In the St. Croix study, several indicators for these attributes declined consistently with distance from the zone of human disturbance. This pattern was recorded at different depths and reef habitats, signifying that the indicators were relatively

immune to changes in microhabitat (Fisher et al. 2008). Although this may not always be the case, robust indicators can overcome the need for classification (sorting reefs by habitat type) which simplifies survey designs and reduces the number of stations that must be surveyed.

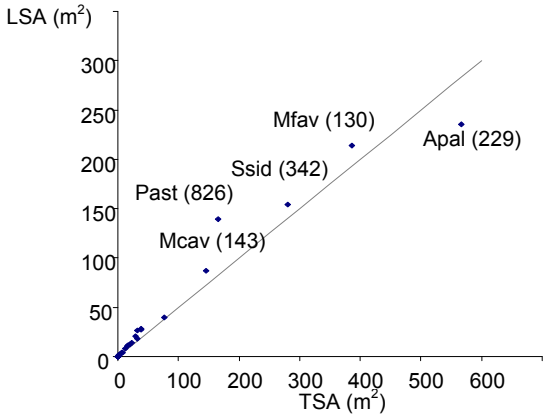

Figure 4. Comparison among coral species of live surface area (LSA; m^2) and total surface area (TSA; m^2) recorded for all colonies found at 29 stations in the Florida Keys (Mcav-*Montastraea cavernosa*; Past-*Porites astreoides*; Ssid-*Siderastrea siderea*; Mfav-*M. faveolata*; Apal-*Acropora palmata*. Colony numbers for each species are in parentheses and the dotted line represents 50%LSA.

Resource managers often focus on the condition of stony corals because they form the infrastructure of the reef and directly provide ecosystem services (e.g., shoreline protection, biological diversity, fishery harvests, and tourism). Stony corals are therefore appropriate for regulatory bioassessment. Stony coral condition has been quantified many different ways, but the RBP is unique in providing both colony and surface area data—each bearing a different subset of relevant management information. For example, the RBP includes measurements to estimate colony size, providing information on reef structural complexity, population structure and even historical condition. Likewise, the RBP includes estimates of live and total surface area, which can be used to characterize colony health and potential for growth and reproduction. The two approaches can even be combined to illustrate otherwise undocumented characteristics, such as size-related health (Fig. 3).

Colony size is sometimes ignored in coral monitoring programs, even though size provides highly relevant management information. For example, size can be used to demonstrate the size classes and species with the greatest physical capacity for growth and reproduction. In an example from the Florida Keys survey (Fig. 2), medium-sized colonies had higher LSA than small or large colonies. Areas with medium sized colonies might be expected to recover more quickly (resilience) from a bleaching event. A region with large colonies (even large, dead colonies) indicates that historic environmental conditions were capable of supporting vigorous or prolonged coral growth. A region with small colonies and low abundance may have experienced more persistent, chronic stresses. Presence of large colonies with low proportions of live tissue could indicate a region with historically good environmental conditions that suffered some catastrophic event, such as a hurricane or massive bleaching. A likely example of this was found for *Acropora palmata* at Florida Keys, a situation that was previously noted by Fisher et al. (2007). Large *A. palmata* colonies exhibited much lower %LT than large colonies of other coral species (such as *Montastraea faveolata*; Fig. 3), indicating differential sensitivity to the stressor. Smaller colonies exhibited high %LT, indicating a return to pre-event conditions for newly recruited colonies.

The plight of *A. palmata* colonies in Florida Keys was also evident—on average, colonies had less than 50% live surface area (LSA/TSA; Fig. 4). This is particularly important for resource management, not only because *A. palmata* are listed as threatened species, but also because they likely contribute more than any other species to shoreline protection, community habitat, biodiversity and tourism. Other species (e.g., *M. faveolata*) have better health but with lower TSA do not contribute as many services. Further, *A. palmata* may be critical to reef sustainability. Done (1997) claims that reef sustainability is driven by two key variables, reef framework and reef-building capacity. Elkhorn corals have already lost reef-building capacity (%LSA) and, with eventual deterioration, will contribute less and less to reef framework (TSA).

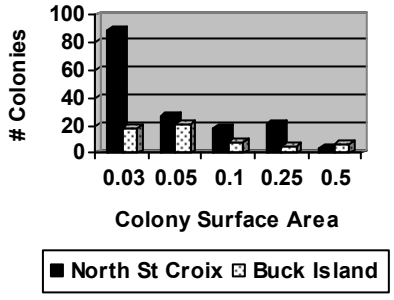

Figure 5. Number of colonies by size class (CSA; m^2) for *Diploria strigosa* from the northern shore of St. Croix (U.S. Virgin Islands) and nearby Buck Island.

Colony size can also used to compare population structure (size-frequency), which identifies populations that have high and low relative recruitment (Fig. 5). Study of population structure over time provides

essential information on population dynamics (Bak and Meesters 1998). Colony size (AvCSA) and colony size heterogeneity (CSA-CV) were among those indicators responsive to human disturbance—both were lower for stations near the center of disturbance (Fisher et al. 2008; Fig. 5). Chronic human disturbance (e.g., pollution, physical damage, overfishing) may not always inhibit coral recruitment, but poor environmental conditions will likely lead to reduced growth rates and shorter life spans.

The RBP indicators exhibited significant potential for monitoring programs, regulatory standards and management utility. Although application to other locations and environments is needed, these studies complete a first step toward development of tools for coral reef biocriteria.

Since the 1980s, there has been growing recognition that water quality standards based on chemical criteria alone cannot protect biological resources (Karr 1991). This has stimulated efforts to develop biological assessment methods and to implement biocriteria. Many states and territories now fulfill the regulatory requirements of the CWA to document the condition of streams, lakes, and estuaries through local and even regional assessments of fish, macroinvertebrates, and algae (EPA 2002). Similar programs for coral reefs can be developed and implemented to provide useful management information and long-term records of coral condition and regulatory compliance.

Whereas global climate change is a major threat (Hoegh-Guldberg et al. 2007), efforts must continue to protect coral reefs from local stressors originating in the watershed and coastal zone. This compels use of the most powerful regulatory tools available. The Clean Water Act provides U.S. states and territories the legal framework and regulatory authority to designate waterbody uses specific to coral reef resources, to track status and trends using biological indicators, and to identify impaired waterbodies. Ultimately, the CWA has the capacity to trigger restrictions on diverse human behaviors that could physically damage or send toxics, nutrients, sediment, and pathogens into coral environments. The CWA is a potent regulatory tool with an expressly defined purpose—to protect aquatic life. With defensible scientific underpinnings, the CWA should be at the forefront of U.S. coral reef protection.

Management and monitoring for coral reef conservation in the Port of Singapore

N. Goh

Coastal & Marine Environment Programme Office, National Parks Board, 1 Cluny Road, Singapore 259569, Singapore

Abstract. Since its founding in 1819, Singapore has lost an estimated 60% of its coral reef area. Most of this loss is attributed to pressures from land-use necessitated by an increasing population and a fast-growing economy. Nevertheless, high species diversity remains on coral reefs, with more than 250 scleractinian species still extant. This number is more noteworthy as Singapore's total coral area covers only 1000ha. In earlier years, conservation of coral reefs was incidental, contrasting with a more intentional approach today. A major pillar of this new approach involves the setting of strict environmental quality objectives and use of real-time feedback monitoring processes. These rigorous environmental monitoring and management plans allow mitigation of impacts while allowing coastal development that is often necessary in a land-constrained situation, even when these developments are in close proximity to such reefs. In Singapore, the problem of having many stakeholders in coastal areas is exacerbated by the intensity of use resulting from very limited availability of land and coastal areas. Besides traditional coral reef conservation, approaches like active habitat enhancement measures are necessary to ensure long-term sustainability of coral reefs in the face of these pressures.

Key words: Coral, Management, Port, Feedback monitoring

Introduction

Singapore is an island nation with a land area of about 700km^2 and a population of approximately 4.8 million (Statistics Singapore 2008), giving rise to a population density exceeding 6800/km^2. This intense population pressure, coupled with the need to provide a means of income for people represent the socio-economic realities that need to be taken into account when considering conservation needs.

Modern-day Singapore was founded in 1819 by Stamford Raffles of the British East India Company, who recognized its strategic location and natural harbor. Since then, much of the coastline has been transformed from mangroves and coral reefs to one dominated by development, in particular by extensive port facilities in the south of the island. Most of the nation's coral reefs are also found off the southern coasts. An estimated 60% of the original reefs have been lost (Chou 2007).

Impetus to Conserve Marine Biodiversity

Historically, most coral reefs in Singapore were lost due to habitat destruction. Today, factors that could impact coral reefs here include land reclamation, sewage and other high nutrient effluent, industrial effluent (pollutants as well as industrial cooling water), and oil discharges from ships. One major factor is a high level of sedimentation in the water that has a smothering, as well as light attenuation (Chou 2007) impact on hermatypic corals.

In addition, management of coral reefs in Singapore is complicated by the large number of stakeholders: different government agencies hold jurisdiction for different aspects of coral reefs related to the conservation of the latter; private corporations with coastal facilities also have a stake in some coral reefs; nature or recreation groups with coral reef interests also add their voices to the stakeholder community.

In spite of these pressures and complexities in management, coral reefs and other marine habitats have shown resilience and exhibit diversity that can be considered remarkable. More than 250 species of hard corals are present in Singapore; 31 mangrove plant species, together with 11 seagrass species have also been recorded (unpublished data). Fig. 1 shows the locations of coral, mangrove and seagrass habitats in Singapore. While abundances may have declined, species richness can be considered to have remained relatively stable over the last four decades (Chou 2007).

While the continued presence of such rich biodiversity in the light of a worldwide trend of decline is a cause for optimism, it also leads to the responsibility to ensure its conservation is given commensurate consideration.

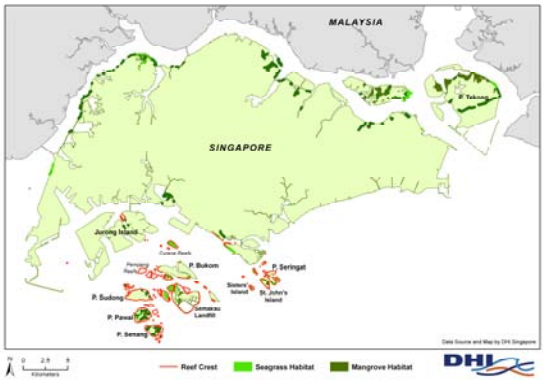

Figure 1: Singapore, showing locations of coral reef, seagrass and mangrove habitats.

Conventional Conservation Approaches Inadequate

Traditional conservation paradigms are largely dependent on protecting areas that possess significant biodiversity by designating such areas as 'no-take' or 'no-go'. In the situation specific to Singapore, i.e., multiple stakeholders coupled with size constraints leading to limited options, intense use-pressures and threats, a more holistic management approach is needed to supplement conventional conservation strategies. This type of approach is likely to be necessary to meet the challenges of conserving coral reefs that occur in close proximity to port or urban centers like Singapore.

Protection of Marine Habitats in Singapore

Prior to 2004, especially in the early days after the founding of Singapore as a port and trading post, there was very limited focus on conservation of coral reefs or other marine habitats. Any government conservation or habitat protection efforts for coral reefs was fortuitous – the result of areas being overlooked in development rather than any conscious motivation to preserve the habitat. One significant milestone related to marine conservation in Singapore occurred in 2004 with the formation of a section dedicated to this purpose in the National Parks Board (hitherto concerned with an almost exclusive terrestrial focus), marking the start of governmental intervention on the part of marine conservation.

In terms of protection of biodiversity from physical development works on coral reefs and other coastal habitats, various international best practices have been adopted in setting out the requirements for approval of such works. For each such development project approved, environmental quality objectives (EQOs), including those related to biodiversity, are set based on current information on the biodiversity at and around the development site that could potentially be impacted ('biodiversity baseline'). The EQOs will typically spell out the level of impact allowed in relation to the project ('no impact' (where no change in the quality or functionality of the habitat if expected using numerical models, and none can be detected in the field) in most cases). Compliance with these EQOs is tracked using monitoring surveys (e.g., by line-intercept transects) and other relevant impact assessment methods (e.g., measurements of water turbidity or sediment settlement). Proposed measures to mitigate any anticipated impacts are also required at pre-approval stage.

In one example of a port expansion project off the southern coast (DHI 2005), which included a land reclamation component, hydrodynamic modeling during impact assessment studies indicated that impacts from the original reclamation profile could be significantly reduced if a different profile was adopted. The original profile was subsequently altered. In addition, the reclamation sequence was optimized to minimize impacts on a nearby coral reef habitat. More than a dozen coral reef sites around the development area are regularly monitored during the period of development, and for 12 months after project completion to ensure that there are no impacts on coral reefs in spite of all the measures imposed. One of the EQOs related to this project was to ensure that suspended sediment coming out of the project site should not exceed a pre-determined level, monitored by turbidity sensors located around the site.

In such projects involving reclamation or dredging where control of suspended sediment is considered important, the conventional approach to control is to impose a cap on dredging or soil dumping rates. Such caps focus on work effort and are presumed to relate to the actual sediment released into the water in a linear and predictable manner. However, this is dependent on a number of assumptions (e.g., on sediment type, current direction and strength, and other ambient environmental factors) that may not hold in all situations. Suspended sediment rates may actually exceed acceptable levels even when contractors are completely compliant with the work effort rate limitations imposed. On the other hand, if the assumptions are overly conservative, the project may drag on longer than actually necessary, leading to impacts caused by the length of time sensitive habitats are subjected to low levels of stress from the development works.

Where it is impossible to prevent destruction of a particular coral reef, every effort is made to minimize the loss of living corals. This is

considered a management imperative, given the very limited extent of coral reefs in Singapore. Controlled translocation of coral reef organisms, with proper monitoring of success (Doorn-Groen et al. 2007) is used in such situations where a coral reef is to be destroyed after consideration of the trade-offs in the decision.

Science-Inspired Approach Towards Long-Term Sustainability of Coral Reefs

Management decisions in Singapore are guided by extensive recent baseline coral reef surveys that cover a majority of the coral reefs here. Regular monitoring is also ongoing for more than a dozen coral reef sites (within a total area of just above 1000ha (unpublished data) of coral reefs in Singapore). This is a very intensive level of study for a very small area; at the same time, hydrodynamic modeling studies covering most of these reefs are also used in management decisions, reflecting the commitment to science-informed decision-making.

Taking advantage of advances in science and technology, a real time suspended sediment feedback system comprising the turbidity sensors mentioned earlier, coupled with a hydrodynamic model incorporating ambient environmental information (Doorn-Groen and Foster 2007) is now used regularly in Singapore. This allows control to be based on the actual level of suspended sediment, rather than on an indirect factor like rate of dredging or soil dumping.

Line-intercept transects are a widely used method of quantifying the abundance (and type) of flora and fauna on coral reefs. In Singapore, results from surveys using line-intercept transects at the reef crest had been considered representative of coral reef health and diversity and used in making management decisions, even though this method only describes a narrow band of life at the coral reef crest. However, studies have shown that on many coral reefs in Singapore, a rich abundance of organisms exists at depths below the reef crest (Goh and Chou 1994, 1995; Goh et al. 1997). As a result of taking such knowledge into account, a new 'Lower Reef Survey' that estimates the rich sponge, ascidian, soft coral and gorgonian fauna has been incorporated in management-related surveys since 2006. This allows survey results used in management decisions to better represent the actual species abundance and diversity situation present on the reefs studied.

Besides stringent measures to enhance the protection of marine habitats (including coral reefs) and the use of existing knowledge of, and advancements in science and technology to enhance conservation management decisions, Singapore has also adopted a management strategy of taking proactive actions to help ensure the long-term sustainability of habitats like coral reefs.

Fragmentation of coral colonies occurs continuously on coral reefs, whether by natural or anthropogenic causes. Based on the foundation of years of research on artificial reefs and recruitment (Chou 2007), a coral nursery was established in Singapore in July 2007 as part of a partnership between the National Parks Board, the National University of Singapore, the National Environment Agency, and Keppel Corporation. Besides studying fragmentation patterns, the project aims to rehabilitate coral fragments collected from reefs throughout Singapore by keeping them at the coral nursery until they are healthy, then transplanting back to natural reefs to enhance natural coral populations.

A study of larval dispersal patterns in Singapore was commissioned to provide information on the genetic connectivity between different reefs in Singapore. Preliminary results from this study are described in Tay et al. (2008). This information will enable management actions (like enhancement transplantation) to be targeted where it will have the greatest impact.

Ultimately, even a large number of individual actions may not have the effect necessary to ensure long-term sustainability of coral reefs in Singapore. An approach to management of coral reefs and other coastal areas that is integrated to include all relevant factors is needed to ensure that such areas can be managed properly. The need for integrated coastal management is well known among scientists and managers globally, and was recently highlighted again by Chou (2007). At the close of this discussion on coral reef conservation within the waters of a busy port, it is good to remind ourselves that while we are mindful of the impacts of port-related activities, like shipping, on sensitive coral reef habitats, an estimated 80% of anthropogenic pollution in coastal areas actually originates from land-based rather than ship-based sources (UNEP GPA 2008).

Conclusions

The limited area, sizeable population, and pace of development in Singapore represent the geographical and socio-economic realities facing conservation proponents.

A holistic approach is needed. In particular, priorities of industry/port development, housing and recreation, and concerns for the protection of coral reefs need to be balanced. This means that some reefs may need to be destroyed in the face of

these societal needs. This also means that 'business as usual' will not be sufficient to ensure the conservation of this globally-threatened ecosystem in Singapore. The intentional, science-based proactive approach discussed above is necessary to ensure the sustained existence of coral reefs in Singapore and other areas sharing similar situations where intense anthropogenic pressures are unavoidable but the will to conserve is present.

Acknowledgements
The idea for this paper arose from many informal discussions among colleagues in the National Biodiversity Centre, National Parks Board and other government agencies, and with collaborators from various institutions on the projects mentioned here, as well as others, which were not specifically referred to in this paper. The manuscript also benefited from the comments of two anonymous reviewers.

Systematic Marine Conservation Planning: towards a marine representative areas network in Nanggruh Aceh Darussalam, Indonesia

Yudi Herdiana[1], Stuart Campbell[1], Andrew Baird[2]

1) Wildlife Conservation Society – Indonesia Program, Jl. Burangrang 18, Bogor 16151, Indonesia
2) ARC Centre of Excellence for Coral Reef Studies, James Cook University, Queensland, 4811, Australia.

Abstract (270). A turbulent history and geographic isolation have prevented systematic surveys of coral reef resources in the Indonesian province of Nanggruh Aceh Darussalam (NAD). Following the Indian Ocean Tsunami (IOT), ecological studies revealed that while most marine habitats where unaffected by the tsunami, many reefs were seriously degraded as a result of decades of destructive fishing and poor coastal development. The recovery of these degraded reefs following dramatic reductions in human activity as a result of the IOT is remarkable. Ironically, socio-economic recovery in NAD is re-introducing anthropogenic threats as fishing pressure and coastal development increase. Some conservation initiatives are in progress, however, these also pose a threat because they lack coordination and integration. A systematic marine conservation plan is required to allow natural recovery processes to continue and to protect marine resources from emerging threats. Here, we present a preliminary analysis using 'Systematic Conservation Planning' guidelines in which the conservation goal was to protect at least 30% of existing coastal ecosystems. Data for the analysis included ecological, socio-economic and reef resilience data collected from 64 sites within NAD. Spatial information for the analysis was derived from satellite imagery due to an extended coast line, habitat complexity and variation in accessibility to sites throughout the region. The optimal approach identified was the establishment of many small marine protected areas (MPA) as opposed to a few large areas. This work provides a solid basis for the establishment of a network of MPAs to achieve these conservation goals for the region and protect and enhance livelihoods.

Key words: coral reefs, MPA, marine conservation, tsunami

Introduction

Sumatra has some of the most diverse coral reefs in western Indonesia where the marine fauna, in particular reef fish, includes a unique mix of species from the Indian and Pacific Oceans (Brown 2007). For example, of the 2057 species of reef fish recorded in Indonesia 60% are found in Sumatra (Allen and Adrim 2003)

The province of Nanggruh Aceh Darussalam (NAD) encompasses the northern third of Sumatra. Coral reefs in the province are concentrated in three areas; Pulah Weh and Pulau Aceh off the northern tip of Sumatra; Simeulue Island and Banyak Islands in the south west of the province; plus extensive fringing reefs along the Sumatran mainland (Fig. 1 and Spalding et al. 2001).

Following the Indian Ocean Tsunami (IOT), ecological studies revealed that while most marine habitats where largely unaffected many reefs in NAD had been seriously degraded as a result of decades of destructive fishing and inappropriate coastal development (Baird et al 2005; Campbell et al 2007, Hagan et al 2007). Subsequent research indicates that these degraded reefs have recovered remarkably well, with up to 5 fold increases in coral abundance since 2005, presumably as a result of the dramatic reduction in human activity caused by the IOT (Ardiwijaya et al 2008). Ironically, as socio-economic activity gains pace in NAD anthropogenic threats to reefs, such as fishing pressure and coastal development, are increasing. While some conservation initiatives are in progress, these also pose a threat because they lack coordination and integration.

The aim of this study was to conduct a systematic marine conservation analysis to provide a framework within which the natural recovery processes of the marine environment could continue, and existing marine resources be protected from these emerging threats. Given the preliminary nature of this analysis the objectives and targets were set following discussions among scientists only. Future spatial analysis will include targets and objectives of all stakeholders.

Material and Methods

Conservation spatial planning analysis was conducted using the GIS based tool, MARXAN, integrated with ARCView 3.3 software. Data sources for the analysis included numerous ecological and socio-economic variables, collected between 2006 and 2008 (Table 1).

Ecological data was collected from 64 coral reef sites throughout NAD. As required for MARXAN, we divided variables into 'habitat' layers and 'cost' layers. Habitat layers are those considered when selecting areas for protection and cost layers are those that are likely to affect the costs of including the area in the final spatial solution (Table 1).

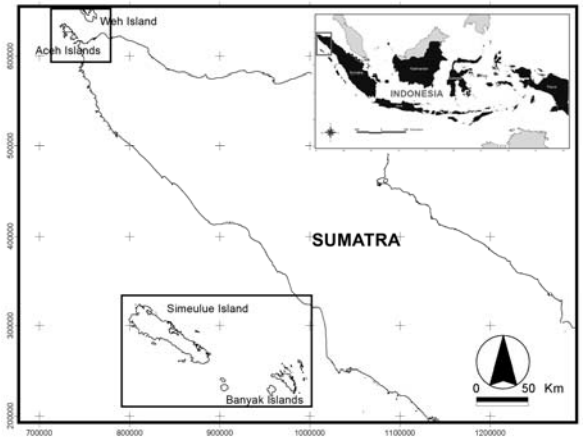

Figure 1. Northern Sumatra with regions of major reef development highlighted by boxes.

Habitat layers	Cost layers
Live coral cover	Distance to village
Coral genera diversity	Distance to port
Coral recruitment	Fishing pressure
Reef fish biomass	Aquaculture
Reef fish abundance	Direct threat (coral mining)
Reef fish species richness	Crown of Thorn Starfish
Clam abundance	
Reef ressilience	
Aggregation sites of Napoleon fish	
Aggregation sites of Bumpedhead parrotfish	
Aggregation sites of Trevaly (*Caranx sp* .)	
Known sites of Manta ray	
Known sites of Whaleshark	
Known sites of Sea Turtle	
Mangrove	

Table 1. A list of the parameters included in MARXAN analysis.

Analysis

For spatial analysis in MARXAN, conservation features were defined by 'bioregion' i.e. a cluster of reefs which have similar characteristics in terms of benthic assemblages and geography (Meerman 2002). This approach was chosen because of the need to analyze many ecological variables (live coral cover, coral diversity, coral recruitment, reef fish biomass and abundance, invertebrate abundance, and reef resilience) based on ranked condition (very good, high, medium, and poor) rather than presence or absence. For the remainder of habitat and cost layers the spatial analysis was performed using presence or absence data.

Spatial data preparation

Quantitative data from the ecological surveys and socio-economic data was converted into four ranked categories (se above). These categories were then incorporated into the previously defined bioregions. Using this approach, each parameter creates four different spatial layers, representing its ranked condition.

Conservation objectives and target

The conservation objectives that we set out to achieve with the analysis were: (i) to conserve 15 to 20% of reef area in total plus (ii) conserve more than 50% of the 'best' habitat. The highest target was set for the best condition for each of the habitat layers representing ecological data and presence or absence of charismatic marine megafauna including Napoleon Wrasse, Bumpedheaded Parrotfish, Trevally, Manta ray, Whale Shark and Sea Turtles. A list of the parameters and targets is presented in Table 2.

Cost Features

Different weightings were given for the four cost values: distance to village, distance to port, fishing pressure (line and net fishing), following the equation:

$$TCF = 2P + 8N + 0.5L + 2V$$

where:

TCF = Total Cost Value
P = Port
N = Net fishing
L = Line fishing
V = Village

The following parameters were 'locked out' to prevent MARXAN selecting areas with these parameters as priority areas; aquaculture, coral mining, and outbreaks of *Acanthaster planci* (COT). Active outbreak levels of COT were defined as an abundance of adult starfish (>15cm in diameter) of over 30 individuals per ha (IUCN, 2004).

Species Penalty Factor

Once the datasets were assembled we set *Species Penalty Factor* (SPF) values for each conservation target. The SPF parameter is crucial for getting useful results from the analysis. The key point is that SPF values must be chosen so that penalties for missing conservation targets are scaled appropriately relative to each other term in the objective function (Ardron et al 2008). SPF helps MARXAN to define the priority level for each conservation target/feature when selecting priority areas.

We set SPF values to range from 0-100 for all parameters and set a value of 100 for several of the highest biodiversity conditions (Table 2).

Boundary Length Modifier

The Boundary Length Modifier (BLM) is used to improve the clustering and compactness of individual solutions (McDonnell et al. 2005). Higher BLM values mean that selected areas will be more clustered in order to reduce the cost of boundary. In this analysis we set BLM value to 10 to create clustered selected areas.

No.	Parameters	Target	SPF
1	Mangrove	17.00	80.00
2	Live coral cover Low	0.00	10.00
3	Live coral cover Med	72.00	50.00
4	Live coral cover High	100.00	100.00
5	Coral recruit Low	50.00	10.00
6	Coral recruit Med	20.00	50.00
7	Coral recruit High	30.00	50.00
8	Reef fish biomass Very low	0.00	10.00
9	Reef fish biomass Low	0.00	30.00
10	Reef fish biomass Med	80.00	50.00
11	Reef fish biomass High	100.00	100.00
12	Coral diversity Very low	0.00	10.00
13	Coral diversity Low	0.00	10.00
14	Coral diversity Med	53.40	50.00
15	Coral diversity High	70.00	100.00

Table 2. Target and Species Penalty Factor

Results and Discussion

Reef condition on Pulau Weh was the best in the northern region of NAD giving MARXAN many options for the placement of protected areas indicated in pink in Fig. 2. Dark purple areas were excluded from the analysis ('locked out') because of their proximity to ports and/or dense urban populations. Areas in brown were also excluded because these areas are already under management.

In Pulau Aceh (Fig. 3), MARXAN select only 10% of reef area for protection. Sites in Pulau Aceh generally have much poorer coral reef condition when compared to other areas within the region (Baird et al. 2005; Campbell et al. 2007). In this analysis, MARXAN selected areas with the highest coral generic richness, reef fish abundance and resilience. The purple color indicates areas excluded due to proximity to the port.

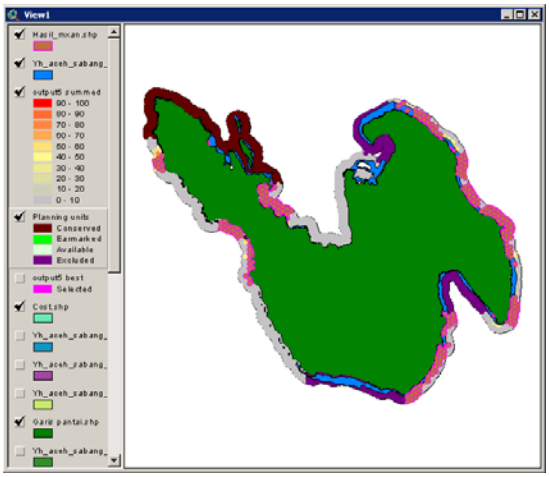

Figure 2. Analysis result of Pulau Weh– northern NAD.

In Pulau Simeulue (Fig. 4), less than 3% of the coastal area was selected by MARXAN. In general, Pulau Simeulue had relatively good reef in some areas, but this result may be affected by limited data. Pulau Simeulue has approximately 300km of coastline and consequently a comprehensive dataset on reef condition is not available.

In Pulau Banyak (Fig. 5), approximately 40% of the coastal area was selected for protection by MARXAN. Areas excluded from the analysis due to proximity to the port or sites of coral harvesting are indicated in red (Fig. 6).

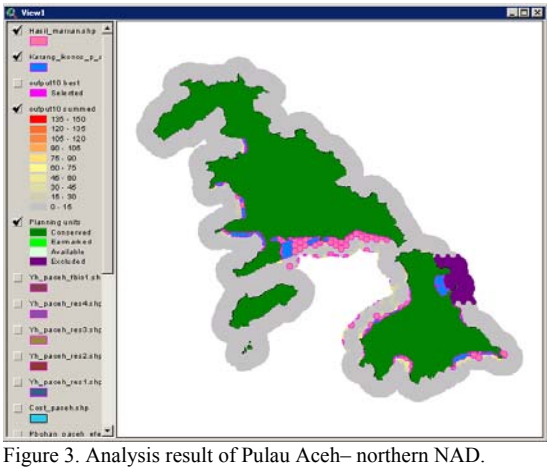

Figure 3. Analysis result of Pulau Aceh– northern NAD.

Conclusion

The analysis identified a ready solution to achieve the limited goals of this preliminary study, i.e. 15 to 20% of reef area conserved in total including more than 50% of the 'best' available habitat. The exclusion of

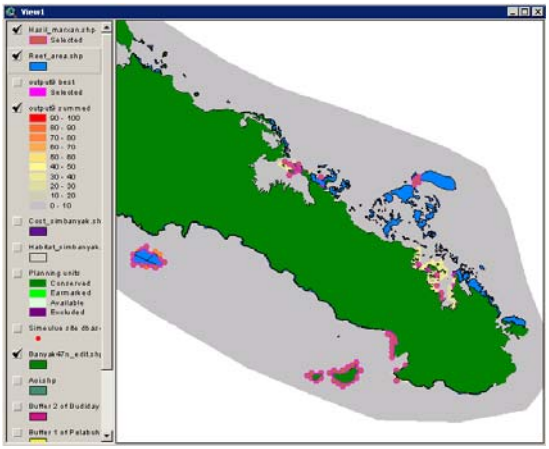

Figure 4. Analysis result of Pulau Simeulue– south-western NAD.

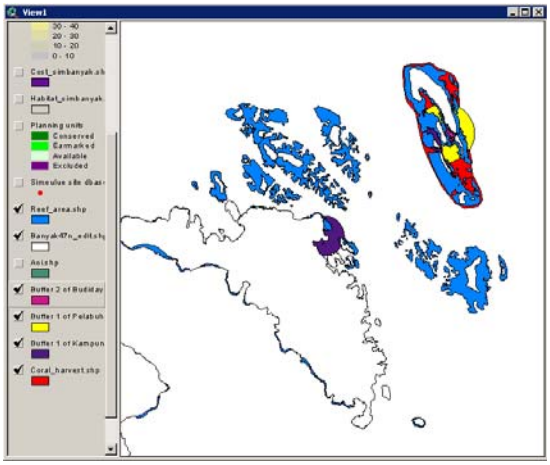

Figure 6. Areas excluded from the MARXAN analysis due to pressure from coral harvesting (indicated by red color).

areas close to ports, high population pressure and conflicting resource use suggests this spatial plan would result in little disruption to other marine resources users and therefore may be a practical solution to the province of NAD's conservation obligations. We must, however, stress that this is a 'first look' conservation plan. Future analyses must seek to consult with other stakeholders to set appropriate targets to achieve a balance between conservation and development in the marine environment in NAD.

Fishery management for artisanal reef fisheries in developing countries: A holistic economic approach

C. Liese

NOAA Fisheries, Southeast Fisheries Science Center, Miami, Florida, USA

Abstract. Traditionally exploited renewable resources in developing countries, in particular artisanal coral reef fisheries, are often difficult or impossible to manage with classical fishery management tools. This paper argues that using the economic perspective to take a closer look at the special characteristics of these fisheries and the decisions that underlie the behavior of the fishing households, a different approach to management reveals itself. A set of feasible policy options, based on a broader economic scale, can be used to indirectly manage for sustainable fishing levels. We summarize some basic economic concepts for a non-economic audience, and apply them to the artisanal reef setting. The central policy implication of these models is that aligning actual incentives faced by fishers with the conservation objective is critical for success (though by no means sufficient). The central incentive "not to fish" is raising the opportunity cost of time of fishing households. Empowering fishers to pursue higher incomes beyond fishing will reduce the effective pressure on the resource. Hence any policy facilitating alternative livelihoods, increasing education or skills, or providing investment grants or credit should be considered conservation policy in and of itself. Further, long-term family planning policies are likely to have the greatest impact.

Key words: Economics, small-scale fisheries, resource management, alternative livelihood, labor supply

Introduction

Most coral reefs are located in developing countries and support a large number of rural fishing households. These labor-intense, small-scale, traditional, multi-species, coastal fisheries---in short artisanal fisheries---are the primary use of the reef. With population growth, development, and globalization these resources are facing tremendous pressures, and their fate rests, to a large degree, on the economic behavior of the fishing households. Unless policy makers intervene directly or indirectly in the decisions of these households, many of these resources will be depleted and possibly permanently damaged or destroyed.

Since the artisanal fishing households are often dependent on the resource and due to their large numbers, failure to sustainably manage these fisheries will have significant impacts beyond purely conservation and fishery concerns. A collapse will create unemployment, poverty, and possibly lead to large population movements. Because the human dimension is so dominant in these artisanal fisheries, it has been argued that they require a modified policy perspective (Tietze et al. 2000; Garcia et al. 2008).

A common characteristic of these resources is that they are being exploited on an open access basis. As bioeconomic theory and plenty of experience have shown, an open access resource will almost inevitably be depleted over time, unless policy makers intervene (McGoodwin 1990). Yet effective resource management is often neither feasible nor practical in a poor developing country setting.

For a variety of reasons, artisanal reef fisheries in poor developing countries are often difficult or impossible to manage with classical resource management tools. This paper is primarily concerned with these situations where successful management, i.e. access limitation of any sort, is not possible. We argue that by taking a more holistic economic approach to the behavior of the fishing households, a different set of policy options becomes apparent. These feasible policies would indirectly manage for a sustainable level of fishing effort. They could potentially conserve the biological health and potential of the resource in spite of it being exploited under an open access property rights regime. The paper is intended to make the case to a broad audience for more involvement of the science of economics when designing conservation policy for reef resources in developing countries. The economic perspective can offer an important understanding of the human actors in these settings.

Bioeconomics and Artisanal Reef Fisheries

Historically, the management of a fishery was treated as a biological exercise. Fishery economics, the bioeconomic approach to renewable resource extraction, began in the 1950s. Seasonal closures,

specific gear restrictions, and other regulations which did not account for human behavioral adaption often further exacerbated the "race for fish" (Homas and Wilen 1997). Economists point to the lack of private or common property rights (conferring the exclusive right to use a resource) as the fundamental culprit of this waste and to market-based tools, such as individual transferable quotas, as the solution. However, the practical importance of this work is limited for the management of artisanal reef fisheries in poor developing countries. First, in many such countries fishery management, in its narrow sense, is simply not feasible. And second, the settings and assumptions that drive the bioeconomic framework often do not apply.

The introduction of effective, modern management to artisanal reef fisheries in many poor developing countries faces many challenges. The first hurdle is a lack of recognition of the actual scarcity of the resource and no legal entity with clear management responsibility. Even if the need for management is recognized, few of the needed financial and administrative resources exist, and there are a plethora of more pressing problems (e.g. acute poverty, disease). The remoteness of locations, the lack of a property rights tradition, and minimal law enforcement make introducing most fishery management tools very difficult. Limited or non-existent data on catch, effort, and the resource status is a further problem. Finally, the costs of creating and running such a system would likely be prohibitive relative to the value of the fishery and the means of many poor developing countries.

Situations where successful management of artisanal reef fisheries is more likely to be feasible---not the primary concern of this paper---are richer developing countries where local marine tenure traditions exist and have government support. If access can be limited, protected areas are of particular promise because they can take account of many of the special characteristics of artisanal reef fisheries.

The bioeconomic framework and the associated management tools are primarily developed for an "industrial" fleet fishing a large single species stock, with a focus on capital investment in vessels and equipment. Fishers are modeled as profit maximizing firms active in perfect markets for capital, labor, and fish. Total fishing "effort" is usually dominated by vessel and gear capacity, with labor playing a secondary roll. All of these assumptions are in stark contrast to the settings found in artisanal reef fisheries in developing countries.

Artisanal fishers are usually small operations in a local, seasonal, multi-species, multi-gear fishery, where single species management is impossible. They use predominantly small wooden boats and basic gear (lines, nets, spears, etc.). Human labor is the dominant input, with capital playing a secondary role. The artisanal fishing households often live in poverty and consume the less-marketable portion of their catch. Further, market failures plague these fisheries. Product markets exhibit high transaction costs due to the remoteness of small fishing communities and the perishable nature of fish, while labor markets often do not exist (Polunin and Roberts 1996).

It should be noted that semi-subsistence, agricultural households, including fishing households, are often characterized as stagnant entities. This is usually far from the truth as they engage in occupational multiplicity and respond strongly to changes in prices and costs. They behave as economic agents, suggesting that fishing is best understood as one productive activity among many (Tietze et al. 2000; Allison and Ellis 2001; Liese et al. 2007).

More recently outboard motors have extended the range of the typical fisher, while monofilament nets have increased the intensity of exploitation. As a result, the effective fishing capacity has increased, but the overall fishing effort in most artisanal reef fisheries is still primarily a function of the labor supplied by the households. Given the predominance of the human dimension, preferences, market aspects, and socio-economic and demographic variables must be taken into account when designing policy. While the bioeconomic approach offers little practical guidance, the economic approach in general can be very helpful.

Effort in an Artisanal Reef Fishery

Given a level of technology, the total effort in a traditional setting can be decomposed into individual and population elements (Kalland 1995). Both are determined by household behavior, yet the relevant decisions are particular to each level. Fig. 1 is a

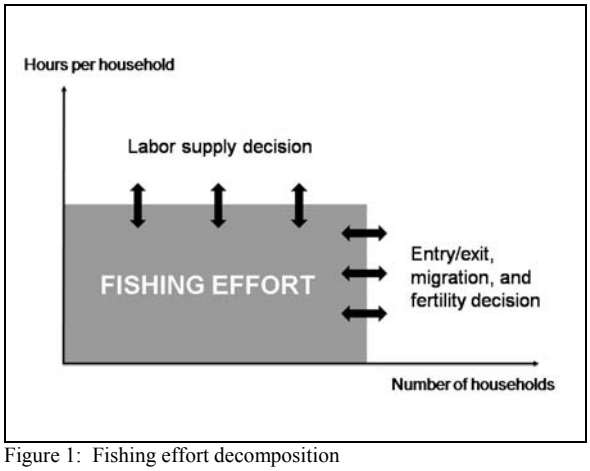

Figure 1: Fishing effort decomposition

stylized illustration of this decomposition of total fishing effort. The representative household's fishing

effort times the number of fishing households leads to the total fishing effort, which is depicted as the shaded area. The individual element is the fishing effort decision by each household, i.e. the intensity of use or hours spent fishing. The population element comprises occupational entry/exit, migration, and fertility decisions. Another way to look at Fig. 1 is as a split along temporal lines. Since traditional fishers usually are independent entrepreneurs, in the short run, the total effort changes due to changes in fishing intensity by existing fishers. Over a longer time horizon, entry/exit into the population of fishers becomes the dominant determinant of the total effort.

Economic Modeling of Labor Supply

The effort decision by a fisher can be modeled in the utility-theoretic framework of micro-economic theory. At the most basic, an individual's utility depends on the consumption of two normal goods, one leisure and one a catch-all for purchased consumption (see any microeconomic text for a more thorough discussion). The individual maximizes his utility by selling part of his fixed endowment of time (i.e. giving up leisure) at a fixed wage rate in order to generate an income with which to buy the consumption good. The amount of labor sold---the labor supply---depends on the wage rate. The wage rate influences the supply through two channels: 1) as the price at which consumption can be substituted for leisure, leading to a substitution effect, and 2) as a determinant of the total wealth (time endowment valued at the wage rate), leading to an income effect. The substitution and income effects have countervailing effects on the labor supply. If this analysis is expanded to include a minimum subsistence requirement it gives rise to the inverted "S"-shaped labor supply function depicted in Fig. 2.

The traditional portion of the labor supply curve is upward sloping, where an individual substitutes consumption for leisure as the wage increases, i.e. as the opportunity cost of consuming leisure increases. In this area, the substitution effect dominates. At higher wage rates the income effect starts to dominate the substitution effect. Starting at this point the labor supply curve becomes backward bending, which is characteristic of richer individuals or economies. If an individual is secure in his subsistence requirement, i.e. income beyond labor income, then his labor supply curve begins with the upward sloping segment. The wage that corresponds to the lowest point is referred to the reservation wage and at wages below this level, the individual will choose not to participate in the labor market.

The "distress sale" portion of the curve would only be observed in a traditional sector of a developing country in the absence of any type of social insurance programs (Sharif 2000; Dessing 2002). This portion of the labor supply curve results if individuals face serious poverty where their only income is through labor, and the wage is less than a living wage. Along this section of the curve an individual only sells his labor due to acute distress. As the wage rises, the individual reduces his supply of labor, as less is necessary to generate the minimum subsistence income. In the fishery context this might reflect a Malthusian overfishing scenario (McManus 1996).

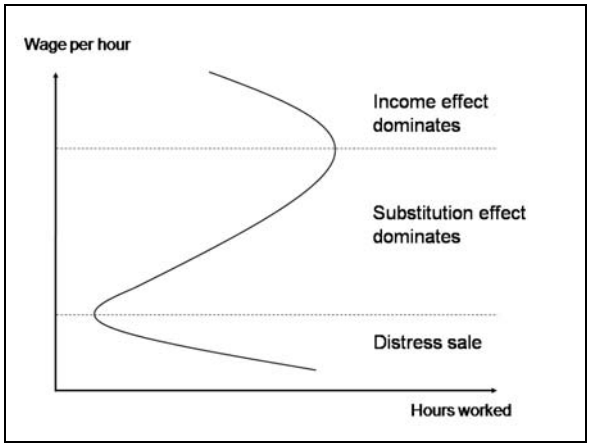

Figure 2: Complete neo-classical labor supply function

In a rural setting of a developing country, few individuals work for a fixed wage as most are self-employed. It seems reasonable that the above neo-classical labor supply relation still explains behavior if one reinterprets the wage as the effective return to labor of a productive activity (net of non-labor costs). For example, the amount of time a person would spend fishing would depend on the implicit wage of the activity, i.e. the productivity of fishing times the price of fish. Differing implicit wages would give rise to a schedule of labor supply roughly corresponding to Fig. 2. The key idea is that developing country households are surrounded by opportunities and challenges in their daily struggle to make a living. In the informal village economies of most artisanal reef fishers, psychic, physical, and material benefits and costs play the same role as financial benefits and costs do in a more formal economy. These incentives drive behavior.

An important disincentive for spending time on any one activity is the opportunity cost of time, which is the value of the time in its next best use. Regardless of whether labor markets exist or not, each individual (or household) faces an opportunity cost of time, be it an implicit wage, an actual wage, or a value for leisure. The possibility of engaging in multiple activities, as is very common in developing countries, can be economically modeled with the help of the time allocation or home production frameworks (Gronau 1977).

Finally, the population of fishers is partly determined by occupational entry/exit decisions. Households enter the fishing enterprise when economic incentives are right and exit when more income (or utility) can be generated in a different profession (Cinner et al. 2008). Entry/exit decisions can be modeled with approaches similar to the ones mentioned above for labor supply and time allocation.

Migration and Fertility

In the long run, migration and population growth are driving forces behind the exploitation of renewable resources (Kramer et al. 2002). These are complex phenomena, and it is a multi-disciplinary undertaking to define, measure, and explain reasons for and consequences of demographic change. In spite of this, population growth must at least be considered, especially since resource conservation is about this long run. Migration among fishers is especially important since it re-allocates fishing effort over space. An important and successful approach to understand and explain population movements is the economic one by framing migration as the outcome of a utility maximizing decision by individuals. At the end of the 19th century E.G. Ravenstein developed six "laws" of migration which have stood the test of time. One of them is "the dominance of the economic motive" for migration (Todaro 1976).

Fertility and mortality are additional forces changing the fishers population level. In the past, fertility has often been the dominant force of change. Population growth without economic development leads to pressure on the natural resources. Even if access is limited, population pressure in such settings has a high potential to undermine any management institutions. Artisanal fisheries are particularly prone to this, as it is ethically questionable to exclude people living at the existence minimum from a potential food source. Examining the fertility decision by households and linking it to economic development is a major topic in demographics and population economics (Becker 1960).

Implications for Conservation Management

Fisheries management is foremost about managing people rather than fish (McManus 1996). As a result, the economic approach---the utility theoretic framework---is central to evaluating the design of any policy aimed at conservation in an artisanal reef fishery. The most important economic contribution to management of reef resources is focusing the discussion on incentives---the factors encouraging, motivating, and inducing behavior.

For any policy to be successful it must align the incentives the fishers face with the conservation objective. Any policy that changes the incentives faced by the fishers by changing relative prices and costs within the fishery will impact the resource status. Since these incentives can be influenced by a variety of non-fishery policies, indirectly managing for a sustainable fishing effort level can be possible. Non-fishery policy instruments in areas such as development, employment, population, and social policy could be tried. Unlike with standard bioeconomic prescriptions, removing the open access nature of the fishery is not necessary. McGoodwin (1990) refers to such policies as "passive indigenous regulation," though he also includes anthropological concepts, such as customs and beliefs.

The central incentive "not to fish" is a high opportunity cost of time among the resource users. In particular, helping fishers find better paying livelihoods raises their opportunity cost of time and will reduce the pressure on the resource. The scope and scale of the labor market can be expanded by creating alternative employment or income diversification opportunities. Other interventions include increasing the education level, providing skills, or raising productivity in non-fishing industries or agricultural (intensification).

The above is related to the alternative livelihood approach, but with the emphasis on fishers being "pulled" out of their profession by better opportunities elsewhere rather than being pushed out of fishing and needing to find other employment. Creating alternative income opportunities should be seen as a conservation policy in itself, rather than just as an add-on to mitigate unwanted side effects of a conservation policy. Policies that empower households and enable them to pursue alternative livelihoods, rather than prescribing specific ones, are likely to be more effective. In addition to education and skills mentioned above, market liberalization, land reform, and providing credit or grants for investment beyond fishing are policies of this nature.

Other policies likely to increase the opportunity cost of time include general development and poverty reduction. With increasing wealth, households will value leisure time more. New entertainment options might also increase the value of leisure time directly. Reducing poverty through income redistribution would probably have similar effects. But caution is warranted. Policies that promote general development will likely also create incentives for households to fish more. For example, improved infrastructure or exposure of artisanal fishers to regional and global product markets can increase fish demand, raise its price, and hence lead to more exploitation (Cinner 2006; Liese et al. 2007). Anticipating the various incentives and disincentives created by a policy and the resulting impact on the resource might be called a holistic economic approach to resource management.

Demographic phenomena are always very context dependent, so general insights for conservation policy are limited. We might risk speculating that policies that set the incentives for households to discourage fishing are likely to have similar effects on migrants' fishing decisions and by extension on the migration decision (if it is motivated by fishing income, as it often is). On the other hand, family- or refugee-based migration is clearly beyond simple economic analysis. Over time, fertility is the central determinant of fishing effort in a poor developing country setting. Three general policy implications suggest themselves: 1. Family planning policies are among the most powerful conservation measures available; 2. any policy with the aim to conserve the reef resource over time must anticipate and be able to withstand demographic developments; and 3. if population growth and in-migration cannot be stopped, access must be limited or the resource will be depleted.

Conclusion

This paper sets out to make the case for more involvement of the science of economics when designing conservation policy aimed at coral reef fisheries in developing countries. This brief paper is in no way a comprehensive or exhaustive review or discussion of this topic. Instead it summarizes some basic economic concepts for a non-economic audience, and applies them to the coral reef setting.

We describe the science of fisheries economics and its serious limitations when applied to a developing country artisanal reef fishery. Instead, we propose that more basic and usually simpler economic models can be more helpful---and in fact critical---for understanding effort in these fisheries. Labor supply and time allocation models can be employed to help explain households' fishing behavior. The determinants of the household's fishing decision can sometimes be influenced by policies, thereby providing possible avenues to indirectly manage for conservation of the resource, even if classical fisheries tool are impossible to implement (which is often the case).

The central implication of these conceptual economic models is that aligning the actual incentives faced by fishers with the conservation objective is a necessary condition for success (though by no means sufficient). In many cases the only feasible incentive "not to fish" is raising the opportunity cost of time of the fishing households. Empowering fishers to pursue higher incomes outside of fishing will reduce the fishing pressure on the resource. Hence promotion of alternative livelihoods, education, skills, and others mentioned should be considered conservation policy in and of itself.

Finally this paper argues that conservation policies that aim for sustainability must take into account the very long run. Over time, demographic developments will usually be the dominant force determining fishing effort in a developing country setting. Conservation policies that ignore demographic pressures are doomed to failure by (lack of) design unless access can be effectively limited.

Contaminants in Fishes from Johnston Atoll

L. Kerr Lobel[1] and P.S. Lobel[1]

1) Boston University, Department of Biology, 5 Cummington St., Boston, MA, 02215 USA

Abstract. This study examined the distribution of military-industrial contaminants accumulating in coral reef fishes in the lagoon of Johnston Atoll, Pacific Ocean. This atoll was a major military base involved in nuclear and chemical weapons as well as being a depot, transient airfield and harbor since the 1930's. The base was closed and abandoned in 2003. Fishes of different trophic levels were sampled from locations throughout the atoll. Contaminants of concern included radionuclides, heavy metals (antimony, arsenic, barium, cadmium, chromium, copper, lead, mercury and zinc) and organic contaminants including; polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), herbicides, dioxins and furans (PCDD/PCDFs). The northwest section of Johnston Island, the largest island in the atoll, was the area with the highest level and variety of contaminants in fishes and sediments. This was near the site of the open burn pit and trash dump, fire training and explosives detonation areas, and the former storage site of Herbicide (Agent) Orange.

Keywords: Central Pacific Ocean, PCBs, PAHs, dioxin, Agent Orange, weapons grade plutonium

Introduction

Johnston is a remote Central Pacific Atoll. The nearest landfall is French Frigate Shoals, 804 km (500 miles) north. The atoll is about 1,287 km (800 miles) southwest of Honolulu, Hawaii and 1,440 km (900 miles) north of the Line Islands of Kiribati. Johnston Atoll (JA) came under military control in 1934 and remained so until 2003. Its use varied during those years but included extensive use as a refueling site, atmospheric nuclear testing, master LORAN station for the Pacific, storage site for unused herbicide orange (agent orange) and chemical weapons, and the incineration of chemical weapons in the Johnston Atoll Chemical Ammunition Disposal System (JACADS) (Lobel and Lobel 2008).

Many of the activities mentioned above, as well as infrastructure needed to support a military and civilian workforce of up to 2000 people, contributed to soil and sediment contamination within the atoll (Lobel and Kerr 2002). Polycyclic aromatic hydrocarbon, petroleum hydrocarbon and metal contamination was associated with refuse burning, fire training operations and fuel storage. Organochlorine contamination due to leakage from discarded electrical equipment, transformers, polychlorinated biphenyl (PCB) contaminated fuel and herbicide orange (HO) were the main contaminants of potential concern (COPC) due to accumulation in top predators and potential toxicity. HO contains two active ingredients, the n-butyl ester of 2,4- dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), as well as the contaminant 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD).

Polychlorinated biphenyls were found mainly in two areas of the lagoon, the west end of Sand Island and in the Navy Pier (tank 49 lagoon) area on Johnston Island (JI), the main island within the atoll. Polychlorinated dibenzo-p-dioxin and dibenzofuran (PCDD/PCDF) contamination in soil and nearshore sediments of the northwest corner of JI was caused by leaking storage drums containing HO (Lobel and Kerr 2002).

Of the four aborted nuclear tests that occurred on JI, two would have contributed to the dispersal of radionuclides into the lagoon. Most of the debris and residual plutonium from the STARFISH event, aborted at 30,000 feet, landed in the water surrounding JI and on adjacent Sand Island. The BLUEGILL PRIME event scattered radioactive material primarily downwind of the launch emplacement. The single residual contaminant was Weapons Grade Plutonium (WGP), which consists of five isotopes of plutonium (238, 239, 240, 241, and 242) and americium-241.

This review summarizes contaminant data in aquatic biota from multiple studies/sampling events sponsored by different agencies. Management responsibility for JA is shared among several agencies including the US Air Force, US Army, US Coast Guard, US Fish and Wildlife Service and the Defense Threat Reduction Agency thus, an integrated approach to ecosystem management including the need for long-term monitoring and potential cleanup is necessary.

Materials and Methods

Samples were collected from sites with known sediment contamination as well as sites with no sediment contamination for comparison (Lobel and Kerr 2002). The main concerns were PAHs, PCDD/PCDFs and metals in fishes from the NW corner of JI and down wind from JACADS, PCBs from the Tank 49 lagoon and Sand Island, radionuclides surrounding JI and Sand Island. Fish sampled from Kaneohe Bay, Oahu, Hawaii served as a reference site for radionuclides.

Sample species were chosen based on food habits or potential for accumulating contaminants, relative abundance and distribution within the atoll. Species sampled included parrotfishes *Chlorurus sordidus, Scarus psittacus, S. rubroviolaceous*; surgeonfishes *Ctenochaetus strigosus* and *Acanthurus triostegus*; the damselfish *Abudefduf sordidus*; goatfishes *Mulloidichthys flavolineatus Parupeneus multifasciatus, P. trifasciatus;* the triggerfish *Rhinecanthus aculeatus;* and the squirrelfish *Sargocentron tiere.*

Fish samples were collected by spear. Individual fish were placed in plastic bags after capture. Each sample location was mapped using GPS then plotted on nautical charts and high definition aerial photographs. Samples were chilled on ice immediately upon collection. Fish were identified to species, weighed and measured (SL). Samples were again cooled to 4°C prior to shipment on dry ice. Quality control samples consisted of approximately 10% of the total samples sent for analysis. Splits, duplicate samples, matrix spikes as well as field, trip, and laboratory blanks were used to determine the precision and accuracy of the analytical data. All analyses were completed by government contract laboratories using US Environmental Protection Agency (EPA) approved methods (USEPA 1993, 1994,1996, 1999; SW-846 method number in parentheses; http://www.epa.gov/sw-846/main.htm). Samples were extracted and separated using methods 3500, 3540(C) and 8000. Chlorinated herbicides were measured with gas chromatography (GC) using methylation (8150). Individual congeners of polychlorinated biphenyls (PCBs) were measured using high resolution GC and low resolution mass spectrophotometry (HRGC/LRMS; 8082A, modification 680 and EPA Method 1668). Total PCBs were taken as the sum of all mono- to decachlorinated congeners. Polychlorinated dibenzodioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) were measured using HRGC/HRMS (8290). Toxicity equivalents (TEQ) for 2,3,7,8 tetrachlorodibenzo-p-dioxin were calculated using fish derived toxicity equivalency

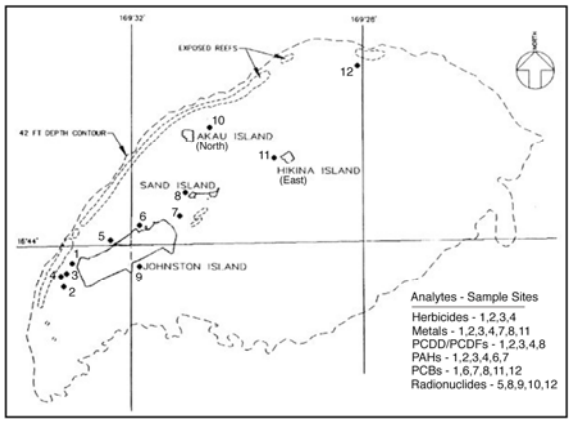

Figure 1. Biota sampling sites within Johnston Atoll. 1) offshore of the former Herbicide Orange (HO) storage area, 2) west camera stand, 3) across the channel from the HO site, 4) inner reef area, 5) offshore of the radiation control area (RCA), 6) tank 49 lagoon area, 7) Buoy 14, 8) west end of Sand Island, 9) south side of Johnston Island, 10) Blue Hole, 11) East Island, 12) Donovan's Reef.

factors (TEF) for 17 2,3,7,8 substituted congeners (Van den Berg et al. 1998). Polycyclic aromatic hydrocarbons (PAHs) were measured with GC/MS (8270). Barium, cadmium, chromium, copper, lead, and zinc were measured using atomic absorption (AA) with direct aspiration (7080, 7130, 7190, 7210, 7420, 7950) while antimony and arsenic used a borohydride reduction (7062). Mercury was measured using the cold vapor technique (7471A).

Radionuclide analysis was conducted by Oak Ridge National Laboratory (ORNL), Grand Junction, Colorado. Whole fish bodies without viscera and the viscera were analyzed separately by alpha spectrometry for ^{241}americium, ^{244}curium, ^{238}plutonium, $^{239+240}$plutonium, and ^{242}plutonium using ORNL procedures PU242 and RC-19 R06.

Results

Multiple sampling events occurred between 1995 and 2003 focusing on different areas of the atoll and differing contaminants (Fig.1).

In total, 94 reef fish samples were analyzed for PCBs, 80 for PCDD/PCDFs and metals, 55 for the herbicides 2,4-D and 2,4,5-T, 65 for PAHs, and 82 for radionuclides.

The herbicides 2,4 D and 2,4,5 T were not detected in any fish tissues. Trace levels of PAHs were detected in fish tissues from sites 1,2,3,4 and

6 but all detections were below the limits of quantification.

The most toxic dioxin congener, 2,3,7,8 tetrachlorodibenzo-p-dioxin (TCDD) was detected in 35% of the 80 fish samples analyzed for PCDDs/PCDFs. Of these samples 79% (27 of 31) of the detections were from offshore of the former

Table 1. Distribution and concentration of A) organic constituents including percent lipids, B) metals and C) radionuclides in Johnston Atoll reef fish tissue and viscera by site. Sample sizes (N) are the number of individual fish analyzed with the number of species collected at each site shown in parentheses. Data are summarized as mean ±sd (range) wet weight (ww). Sample sites are shown in Fig. 1.

Table 2. Comparison of mean PCB, $^{239+240}$Pu, and metal concentrations in fishes from different Pacific locations. $^{239+240}$Pu activity in muscle only from JA fish was calculated based on tissue partitioning factors and muscle mass from Noshkin (1987). Muscle activity = eviscerated fish activity X muscle partition factor (0.045 for surgeonfish and 0.075 for goatfish); Muscle mass = total fish mass X 0.663; Muscle concentration = muscle activity (pCi)/muscle mass (kg).

HO site (1) (Table 1). TCDD was only detected in one other sample (squirrelfish, *Sargocentron tiere*) from site 3. Other PCDD/PCDF congeners and dioxin-like chemicals including mono-ortho and non-ortho PCBs (Zabel et al. 1995, van den Berg et al. 1998) used to calculate TCDD toxicity equivalents (TEQ) were detected in fishes from sites adjacent to the former HO site (2,3,4) as well as East (12) and Sand Islands (8).

Fish tissue concentrations of dioxin related compounds did not exceed environmental concentrations associated with risk to aquatic life. The TEQ in fish tissue was 40.6 pg/g while concentrations associated with low risk to aquatic life is 50 pg/g (US EPA 1993).

PCBs were detected in all fish tissues, but in much higher and more variable concentrations from Sand Island (8) and Tank 49 lagoon (6), sites with known sediment PCB contamination (Table 1). Mean fish PCB concentrations at sites with no known PCB contamination ranged from 12.8 to 36.6 ng/g compared to 1,432 and 753.5 ng/g at contaminated sites. Ecological benchmarks reported for PCB concentrations in whole fish tissue are 0.1, 0.5, and 50 µg/g (Swain and Holmes 1985, Beyer et al. 1996, BCMOELP 1998). PCB concentrations ranging from 2.0 to 6.8 µg/g at site 6 and 0.3 to 3.3 µg/g at site 8 exceed the lower benchmarks.

During the 2001 sampling event all sites sampled (1,7,8,11) contained detectable metals compared to earlier sampling events where only Zn, Ba, and occasionally Hg and Cu were detected. There were no consistent site differences in metal concentrations.

Radionuclide analyses of reef fish specimens revealed that 10% of fish samples and 56% of viscera samples had detectable levels of ^{241}Am activity (Table 1). ^{238}Pu was detected in 16 and 35% of tissues and viscera. $^{239+240}$Pu activity was measured in 32 and 72% of fish tissues and viscera respectively. ^{244}Cu was only detected in one sample respectively from the RCA (5) and Sand Island (8). ^{242}Pu was detected in 6 and 12% of tissues and viscera. Radionuclide activity in reef fishes was highest offshore of the RCA (5). Fewer detections were found in Kaneohe Bay, Hawaii samples although ^{241}Am, ^{238}Pu, and ^{242}Pu activities were similar. $^{239+240}$Pu and ^{244}Cu were not detected in Hawaiian tissue or viscera (Table 2).

Discussion

The objective of this analysis was to provide a summary of the majority of contaminant data currently available for marine fishes from Johnston Atoll. With the exception of radionuclide analysis, fish whole bodies were analyzed to evaluate exposure and bioaccumulation.

Contaminants in fish tissues were greatest at sites with known sediment contamination. Compared to other contaminants, PCBs accumulated to much higher levels in fish tissues than found in sediments. Mean PCBs in sediments from site 6 and 8 were 86.6 and 35.7 ng/g compared to an average of 1432 and 735 ng/g in fish tissues (Lobel and Kerr 2002). In contrast, mean TCDD (at site 1) concentrations in tissues (5.5 pg/g TEQ) were lower than average sediment concentrations (17 pg/g TEQ). These differences may be a function of different levels of contaminant localization.

Radionuclide activity in fishes from JA was detected but low compared to locations in the Marshall Islands where extensive nuclear testing

occurred (Robinson et al. 1997). Ingestion and uptake can still occur however, since the highest radionuclide activities were found within the viscera. Noshkin (1987) suggested that plutonium uptake is lower, or that plutonium is less bioavailable to JA fish since it was produced during an aborted test and is likely a different form compared to the nuclear generated plutonium found at Bikini, Enewetak and other Marshall Island locations.

Assessing impacts of chemical contaminants in coral reef environments is difficult due to a lack of baseline monitoring criteria as well as appropriate screening guidelines for risk assessment (Jameson et al. 1998). Since tropical organisms may not respond to xenobiotics in the same manner or at the same concentrations as temperate organisms (Johannes and Betzer 1975), it is important to both quantify and monitor specific stressors and ecological responses in order to understand concentrations in the field at which adverse effects are observed (Peters et al. 1997).

These data provide baseline information for future surveys and for comparisons of chemical contaminants in the fish biota from Johnston Atoll to fishes in other coral reef habitats. An expanded analysis of this data set will examine the pattern of contamination by species and trophic guild (Lobel and Lobel ms). Long term monitoring is needed since the implications of these contaminants on the reef biota are still being evaluated.

Ecological Effects of the Crown-of-Thorns Starfish Removal Programme on Chumbe Island Coral Park, Zanzibar, Tanzania

C.A. Muhando[1] and F. Lanshammar[2]

1 Institute of Marine Sciences, Zanzibar
2 Chumbe Island Coral Park, Zanzibar

Abstract. Data on reef benthos has been annually collected on Chumbe, Bawe and Changuu reefs close to Zanzibar, Stone Town, since 1992. The data shows that the El Niño in the Indian Ocean in 1997/1998 reduced the coral cover on most reefs with up to 30%. After the El Niño, a slow recovery was noticed until a major Crown-of-Thorn Starfish (COTS) outbreak occurred in 2002/2003 followed by a dramatic decrease in live *Acropora* cover. Only one of the reefs shows an exception – the protected Marine Sanctuary on the western side of Chumbe Island. When the first COTS were seen, the park management immediately initiated an on-going COTS removal programme, which has had a significant positive impact on the reef recovery. On the protected reef, the percent cover of live coral is back on the same level as before the bleaching event. Manual COTS removal programmes are often seen as a waste of time and resources, as their impact are often short term. But the results from this study argue that in a relatively small reef area it is a viable option for maintained or increased reef health and for improving recovery prospects of coral after large natural disturbances.

Key words: COTS, coral mortality, Zanzibar

Introduction

The crown-of-thorn starfish (COTS), *Acanthaster planci*, belongs to the family of *Acanthasteridae*, class *Asteroidea* (starfishes), in the phylum of *Echinodermata*. It is a coral predator causing great damage to coral reefs worldwide when in outbreak condition, e.g. Guam: Chesher 1969; Great Barrier Reef: Pearson & Endean 1969; Japan: Yamaguchi 1986). Their preferred prey is *Acropora* sp. (Endean and Cameron 1990; Pratchett 2001).

Previous records show that Crown-of-thorns-starfish outbreaks were rare events in Tanzania (UNEP 1989). The first reported COTS case occurred in 1988 and only one reef (Pange) was affected (UNEP 1989). Smaller incidences occurred in 1996/97 on Changuu reef, Zanzibar (Mohammed et al., 2000). A serious outbreak started in 2002 on a few reefs close to Zanzibar and then expanded to infest more that 60 % of Tanzania reefs by 2006 including Tanga, Zanzibar, Pemba, Songosongo, Mafia and Mnazi bay reefs (Obura et al. 2004; Mohammed et al. 2005; Obura 2005; Ussi 2008). Unlike in preceding years, the 2002-2006 outbreaks were wide spread and have persisted for a much longer period. Up to now (2008) the Crown-of-thorns-starfish threat has not completely disappeared. Repeated outbreaks have been reported in Zanzibar, Tanga and recently in Mikindani Bay, Mtwara. Such prolonged and frequent Crown-of-thorns-starfish outbreaks are unprecedented in Tanzania. It is not clear whether or not these outbreaks are linked to climate change, overfishing, eutrophication or a combination of all these factors or even just a natural fluctuation in the population.

Instead of waiting for natural processes to control the numbers of Crown-of-thorns-starfish, Chumbe Island Coral Park Ltd. (CHICOP), the managing company of the Chumbe Reef Sanctuary established in 1994, introduced a removal program in 2004 as a way of averting loss in live coral cover. The Sanctuary is relatively small, about 1 300 m long and 300 m wide and the company has trained park rangers stationed on the island at all times. Unlike in other parts of Tanzania (Tanga, Dar es Salaam, and on reefs off Zanzibar town), the removal programme in Chumbe was started immediately after the outbreak; it was consistent and long term.

The impact of Crown-of-thorns-starfish appeared to be enormous and there was an urgent need to carry out assessments more widely. Aside from their potential to cause widespread coral destruction, selective feeding by *A. planci* causes differential mortality among coral species and can exert a major influence on coral community structure (Potts 1981, Moran 1986, Birkeland & Lucas 1990, Pratchett,

2001). One way of revealing Crown-of-thorns-starfish impact is through the analysis of long term trends in live coral cover against the corresponding Crown-of-thorns-starfish outbreaks and other mortality factors. This type of data in Tanzania has been collected annually through existing coral reef monitoring programs, e.g. Scuba based coral reef monitoring at Institute of Marine Sciences (Mohammed et al. 2000, 2002; McClanahan et al., 2007a; Muhando, 2008) or Community Based coral reef monitoring such as the programme existing in Tanga (Horrill et al. 2001). Alternatively, COTS removal programmes offer an ideal scenario to reveal the impacts when sites where COTS are collected are compared with uncontrolled areas. In this study the Crown-of-thorns Starfish Removal Programme on the protected reef on Chumbe has been studied to reveal its ecological impacts on live Acroporids and non-Acroporids by comparing benthic data with data from other unprotected nearby reefs. The specific objectives of this study were: i) to analyse coral reef monitoring data collected by Institute of Marine Sciences and to establish trends in live coral cover of *Acropora* and non-*Acropora*, ii) compare coral cover changes between reefs where the population of Crown-of-thorns-starfish was controlled (individuals continuously removed) and sites where there was no removal programs.

Material and Methods

This study was conducted on three nearby (14-16 km) reefs: Chumbe, Bawe and Changuu reefs, located on the west coast of Unguja Island (Figure 1). A consistent and long term Crown-of-thorns-starfish removal program was initiated on the Chumbe Reef Sanctuary (no-take) reefs in 2004. Bawe and Changuu reefs were not protected from Crown-of-thorns-starfish impact in any way. Data on live coral cover of *Acropora* and non-*Acropora* from 1994 to 2008 was obtained from the Institute of Marine Sciences coral reef monitoring database. Reef benthos (*Acropora*, non-*Acropora*, soft corals, calcareous algae, fleshy algae, sponges, dead corals, etc) was recorded using Line-Intercept Transect (LIT) method. The density of macro-invertebrates including Crown-of-thorns-starfish were also recorded. Additional density information was obtained from other researchers in the study area (e.g., Ussi 2008). Important environmental factors likely to influence large scale coral mortality, such as SST were recorded using Tid-Bit Stowaway temperature loggers since 1997. Two major intersession events occurred: the 1998 coral bleaching event (Muhando 1999; Mohammed et al. 2000; Wilkinson et al. 1999) and the 2002-2006 Crown-of-thorns-starfish infestation (Ussi 2008). Impacts of these events on coral reefs were reviewed from various studies conducted in the study areas.

Crown-of-thorns-starfish removal on the Chumbe reef was carried out by resident park rangers while snorkelling. Chumbe reef is relatively shallow and rangers used handmade wooden sticks and recycled rice bags to carry out the removals. All removed Crown-of-thorns-starfish were counted, measured and then buried on the beach sand.

Results

Coral cover

The reef benthic data shows that all studied reefs had around 50-60% total live coral cover back in the early 1990's (Figures 2a 2b and 2c). The first decrease of *Acropora* cover was noticed on Changuu in 1996 when the first isolated COTS outbreak took place (Figure 2a). Since then *Acropora* have not recovered due to long term presence of COTS and Changuu reef is now dominated by *Porites (*mostly *P. cylindrica*, *P. rus* or *Synarea rus*) and *Galaxea astreata*. Only a slight decline in *Acropora* occurred in Bawe as a result of the 1998 coral bleaching, which was mild compared to the bleaching that took place on Chumbe (Figure 2c; Muhando 1999). On Bawe, *Acropora* cover remained stable at about 21 % until Crown-of-thorns-starfish outbreak in 2003. Since then the *Acropora* cover has declined steadily down to 1-2 % in 2007 and 2008 (Figure 2b). The impact of the 1998 El Niño related increase of seawater temperatures about 2-3 ^{o}C above average (Muhando, 1999) was highest on Chumbe, where around 50% of all corals bleached and up to 90% of *Acropora* species bleached (Muhando, 1999; Mohammed et al., 2000) with total mortality of about 30% (Figure 2c). Unlike in other sites where *Acropora* abundance has substantially declined, the removal program at Chumbe prevented COTS destruction resulting in steady recovery of *Acropora* and non-*Acropora*. Figure 2d shows an

overview of the *Acropora* cover on all three reefs from 1992-2008.

Trends in non-*Acropora* cover in unprotected areas showed no significant change during both 1998 bleaching and Crown-of-thorns-starfish outbreak (Figs. 2a and 2b). Some species of *Montipora* and *Echinopora* were noticed to immediately colonise the dead *Acropora* framework, while *Porites rus* and *Galaxea astreata* and few other species were less affected by bleaching (Muhando 1999; McClanahan 2007b) and COTS predation.

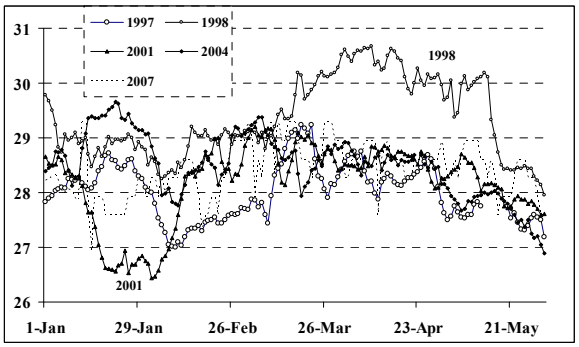

Figure 3: Daily mean seawater temperature (SST) for the months of January-May off Zanzibar town. Elevated seawater temperature in March-April 1998 was associated with coral bleaching and mortality.

Chumbe COTS removal programme

Since the programme started in 2004 a total of 118 collection days have taken place and more than 3,000 COTS have been removed inside the marine park (Figure 4), keeping the densities of COTS to almost zero at all times. Highest number of Crown-of-thorns-starfish removed per month was in January-March 2005 when 661 COTS were collected within the approximately 0.4 km^2 large MPA.

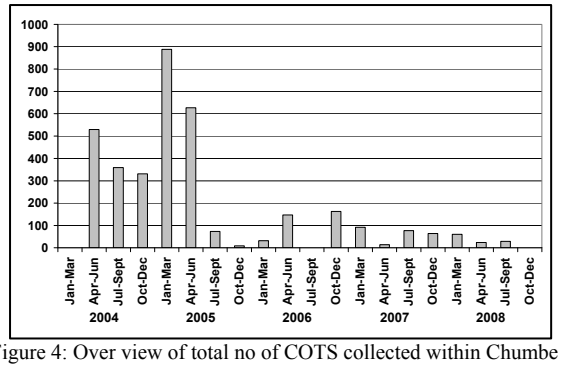

Figure 4: Over view of total no of COTS collected within Chumbe reef sanctuary since 2004

Discussion

Significant changes in *Acropora* cover were linked to the 1998 coral bleaching event (Figures 2b and 2c; Wilkinson et al., 1999) and infestation of Crown-of-thorns-starfish (Figure 2b). This study confirms that the 1998 coral bleaching event and the outbreak of Crown-of-thorns-starfish had more negative impact on *Acropora* when compared with non-*Acropora*. Regeneration of *Acropora* after the bleaching event was halted by outbreak of Crown-of-thorns-starfish, among other degradation factors in unprotected reef areas, while it flourished well in Chumbe where the removal program kept the Crown-of-thorns-starfish density on a low, in addition to other management actions. On the other hand, the removal program didn't have obvious impact on non-*Acropora* corals, at least in the studied areas.

Long term coral reef monitoring data can be useful in linking causes and impacts with natural and human induced disasters on coral reefs. In this study fast decline in *Acropora* was linked to coral bleaching event and Crown-of-thorns-starfish outbreaks. However, non-*Acropora* (as a group) did not show clear links. Such selective mortality has already been demonstrated elsewhere, e.g., McClanahan et al., (2007b) for bleaching and Pratchett (2001) for COTS. *Acropora* seem to be defenceless, easily accessible, palatable, high nutritional value, convenient structure (firm grip against wave actions) and few aggressive/defensive symbionts (Endean and Cameron 1990; Pratchett 2001) and all of the above mentioned features make *Acropora* an ideal target for COTS predation.

When compared to previous outbreaks in 1988 (UNEP 1989) and 1997 (Mohammed et al. 2000), the recent Crown-of-thorns-starfish population outbreak was unprecedented widespread and persisted for longer period. Its persistence and duration appears to suggest a significant environmental change towards favourable conditions for COTS. It is not clear at this stage whether or not this is an indirect impact of climate change (global warming).

Crown-of-thorns-starfish removal program has demonstrated that exclusion of predators can be an effective strategy in enhancing recovery after natural disasters (e.g., El Niño). Unlike in Bawe and Changuu reefs where no clean up action took place, the demise of *Acropora* in Chumbe was rescued. On the other hand, results suggest that non-*Acropora* corals were much more stable. Such differential coral mortality caused by selective feeding habits has a direct influence on reef structure (McClanahan et al. 2007b). In the unprotected study areas the coral composition has changed in favour of *Porites rus* (Synarea), branching *Porites* (*P. cylindrica*) and *Galaxea astreata*. High abundance of Corallimorpharia was noticed on the reef flat and reef slope, covering the dead *Acropora* plates and rubbles (Muhando et al., 2002). *Acropora* is no longer the dominant coral genera today in many unprotected reefs, e.g. Bawe and Changuu. Reef fish that depend directly on *Acropora* for their replenishment are likely to decline as a result (Garpe et al. 2006). The impact of these changes to ecosystem functions requires special research attention.

This study has demonstrated the need to encourage coral predator removal programs, specifically Crown-of-thorns-starfish, as one of the management options to achieve increased coral cover. The removal methodology used was inexpensive and convenient only for shallow water reefs. The use of SCUBA divers is however necessary in case of deeper reefs, though it will increase operation costs. Part of Chumbe success was the decision to initiate the removal at early stages of outbreak along with the continuous monitoring of the reef. Removal programs in Dar es Salaam (Wagner 2004) and in Tanga were not successful because COTS removal was initiated well after significant damage to coral ecosystems occurred. Thus, COTS management requires effective institutional (approving and sponsoring) mechanisms to be in place for making prompt decisions regarding removal programs. Unlike in unprotected areas, the overall management actions within the MPAs also contributes to improved reef health and productivity in the face of human impacts (Russ et al. 2003; McClanahan and Mangi 2000)

Prediction knowledge of when and where *A. planci* outbreaks will occur is still lacking. This is essential to improve future control and increase the chances of success from removal programs. Furthermore, research is also needed to determine factors influencing dynamics of Crown-of-thorns-starfish. For example, a hydrodynamics studies found that due to the interaction of tidal, gravity and wind flows, some areas within the reef retained higher numbers of larvae than others (Black and Moran 1991). Surveillance of these locations, which may be correlated with initial recruitment of *A. planci*, could provide an 'early warning' strategy for monitoring and controlling future outbreaks of this starfish on reefs (Black and Moran 1991). The main long term objective of research at this stage in the western Indian Ocean, is to find out what factors and processes that favour these out-breaks of COTS populations so they can be dealt with and the problem can be avoided before it even occurs.

Acknowledgement

Data on coral cover was collected by the Institute of Marine Sciences with financial support from GEF-Coral Reef targeted

Research and Capacity Building (CRTR) Project. The COTS removal programme on Chumbe was entirely funded by CHICOP. Funding to attend the 11th ICRS was supported by CRTR project and WIOMSA, MARG III grant.

Abstract. To reduce pressure on coral reef resources and economic vulnerability of coastal communities, local fisher women Self Help Groups (SHGs) were empowered through provision of Information and Communication Technologies (ICT) and adult education in 5 coastal villages in Tuticorin district of the Gulf of Mannar (GoM) in South-eastern India. Improved literacy levels, environmental education, as well as the provision of computer training and equipment, enhanced villagers ability to take up alternative livelihoods and improve their living conditions. The support to SHGs demonstrated their potential as a non-threatening mechanism for mobilizing resources, providing affordable finance and social benefits to poorer fisher women, besides promoting self-reliance, awareness creation, capacity development, social solidarity and the empowerment. Village coordinators from five targeted villages were trained and each village was provided with computer, printer, mobile phone, and internet. In addition, the SHG members in the targeted villages were also trained in other alternative livelihood activities such as vermi-compositing and hygienic fish drying methods. The creation of awareness about the environment along with the adult education, computer training and other livelihood options helped the fisher women to earn additional income for their families, the key factor in to reducing the destructive fishing practices and enhancing living conditions in the coastal areas of GoM.

Key words: Reef management, adult education, alternative livelihood, computer education

Introduction

Information and Communication Technology (ICT) is developing fast in India. Government has elevated the livelihood of village folk through a system called Self Help Groups (SHGs) in their respective villages. The SHGs play a major role in the generation, saving and wise use of financial resources. The majority of the SHGs are formed by women and Government encourages SHGs to create confidence particularly among the women. The support to SHGs with ICT can empower them in environmental education (literacy), livelihood options (for socio-economic development), marketing strategies, information on natural disasters and concern about conservation and management of natural resources. Suganthi Devadason Marine Research Institute (SDMRI) in collaboration with Coastal Ocean Research and Development in the Indian Ocean (CORDIO) in East Africa, and Nyköpings Folkhögskola in Sweden initiated the ICT based activities among fisherwomen Self Help Groups in India. The adult education concept has also been tried in other parts of the world as a contributor to national development in Southern Africa (Oduaran and Okukpon 2005); for healthy participative democracy in Scotland (Hammond 2006); and in adult Education and Training in Ireland (Morrissey and McNamara 2004). The aim of introducing the present adult education along with the provision of Information and Communication Technologies in the 5 coastal villages in Tuticorin district of the Gulf of Mannar in the Southeastern India was: 1) to empower local fisherwomen Self Help Groups (SHGs) 2) enhance literacy and livelihood 3) reducing pressure on coral reef resources through greater awareness and education about marine environment and resources 4) minimise overall economic vulnerability of coastal communities.

Methods

Five villages namely, Siluvaipatti, Rajapalayam, Arockiyapuram, Thirespuram and Inigo Nagar were selected in Tuticorin coast of the Gulf of Mannar, Southeastern India. Two coordinators (SHG members) from each village were selected. The coordinators were given training in adult and environmental education and computer applications. After the training, each village was provided with ICT components (including computer, printer, mobile phone, and internet). The coordinators then trained their respective villagers in adult and environmental education; and computer training. The villagers were also given training in alternative/additional livelihood schemes such as vermi-composting and a hygienic seafood drying method. Baseline information on literacy,

occupation, awareness about corals, coral status, destructive fishing practices etc was collected before the start of the activities.

Results

During Oct 2007-Feb 2008, 149 fisherwomen and 6 -men in five villages participated in adult and environmental education was, 34 women and 48 school children in computer education; and 5 women were trained in vermi-composting and 37 in hygienic fish drying.

Participants learned to write their names instead of signing by thumb print; started to read Tamil (local language) and English words; those who already knew to write their names in Tamil learned to write it in English; learned to read bus boards and started to travel alone; learned simple mathematical calculations during adult education classes; women participants are helping their children in their studies; and after witnessing the improvement, more coastal women are willing to take part in the adult education.

The participants of the adult education were taught about cleanliness in their environment and the importance of conservation of natural resources, particularly corals. Increased level of awareness were tested through quizzes and tests. Participants were also made aware of the importance of corals and a clean coastal environment as well as the need for their conservation by way of demonstrating eco-friendly fishing practices, by avoiding disposal of untreated sewage, industrial waste and dumping of solid waste on the coasts. Also information about global warming and its effects on corals was given through video clips and charts.

The programme included group discussion and entertainments (songs, folk dances, drama). The coordinators also participated in the awareness campaign through the National Broadcasting Corporation. Also, women and children received computer classes that met with much success.

Women were taught hygienic ways of sun drying of fishes using indigenous fish drying racks to enhance the quality and price of the dried product. The women in four villages now exclusively use the fish drying racks and the fish, free of dust and sand particles, fetch a better price. In addition, less drying time is required when of drying on the floor.

Village coordinators were trained in vermi-composting and quickly started earning by selling the product in their villages.

The awareness campaign in the five villages bordering Gulf of Mannar had resounding success and resulted in considerably reduced damage on reefs. Shore seine operations, mining and anchoring near the reefs declined. New coral recruits were observed and the live coral cover area is increasing in the once heavily degraded reef areas.

Conclusion

The coral reefs in the Gulf of Mannar are facing various anthropogenic and natural threats but in Tuticorin, several village communities are solely dependent on fish resources obtained from these coral reefs (Shanthini et al. 2002). Crowded fishing grounds, increasing demand for fisheries products, and declining catches often cause fishermen to adopt destructive fishing methods (Samuel et al. 2002) for better results. To counter this trend, the ongoing community based initiative helped to increase literacy level, technical capability in ICT and alternate livelihood practices and knowledge of resource conservation especially eco-friendly fishing, particularly in the reef areas. Fisher folk responded positively to the training initiative and enforcing reef protection has also become easier due to the greater awareness about corals and conservation and environmental education among the villagers.

The creation of environmental awareness along with the adult and environment education, training in computer applications and other livelihood options helped the fisher women to earn additional income for their families, which is key to reduce the destructive fishing practices and enhance living conditions in the coastal areas of the Gulf of Mannar. This pilot effort helped the fisher folk to change attitudes resulting in considerable reduction in disturbance to reefs and surrounding habitats as evidenced by new coral recruits and increased live coral cover.

Abstract: In order to mitigate for anticipated burial of natural hardbottom due to the Broward County Shoreline Protection Project, 3.6 x 10^{-2} km^2 (8.9 acres) of mitigative artificial reef were constructed in August/September 2003. To determine if the artificial reef was approaching community similarity to the surrounding nearshore natural hardbottom, benthic biological monitoring was conducted over five years at six discrete monitoring events. Twenty-seven, 30-meter transects were monitored on the artificial reef and 26, 30-meter transects were monitored on the natural hardbottom. Benthic monitoring utilized the Benthic Ecological Assessment of Marginal Reefs (BEAMR) methodology. The faunal and floral benthic community remained significantly distinct between the artificial and natural reefs five years post-mitigation; however similarity has increased notably over time. Changes in the biotic benthic community structure have slowed on the artificial reef and may be reaching stabilization. The ultimate limiting factor in community similarity between the artificial reef and the surrounding natural hardbottom may be attributed to the differences in structural complexity.

Key words: artificial reef, natural hardbottom, similarity, functional groups, benthic community

Introduction

Ecologically, there is an expectation that an artificial reef will resemble or exceed local natural environments over the long-term as assemblages associate with its surface, structure, and surrounding water column (Seaman and Jensen 2000). Long-term studies are essential to determine possible differences between artificial and natural reef communities.

Common initial settlers of artificial reef such as hydrozoans, polychaetes, mollusks, bryozoans, tunicates, and sponges constitute a 'minor' benthic component (percent cover) but are important in elevating the structural complexity of the artificial reef substratum, eventually establishing an area for coral settlement (Perkol-Finkel and Benayahu 2005). Connell and Keough (1985) found that recruitment of benthic flora and fauna onto an artificial reef occurs primarily by migration from adjacent substrate and by the settlement of spores and larvae. Physical factors such as currents, water depth, and the quality of the substrate influence the recruitment of benthic species onto the mitigation reef. Young (1995) suggested that the introduction of new substrate contributes to an increase in epibenthic organisms which, in turn, provide a larger quantity of food.

Due to the anticipated impact to natural hardbottom areas during beach renourishment activities in Segment III of the Broward County Shore Protection Project (SPP), the Florida Department of Environmental Protection (FDEP) required the placement of 3.60 x 10^{-2} km^{-2} (8.9 acres) of mitigative artificial reef in the nearshore environment. Segment III is approximately 10.97 km (6.8 miles) in length and is located between Port Everglades and the Broward/Miami-Dade County line in south Florida (Fig. 1).

The mitigative artificial reef was constructed as one layer of limestone boulders (1.2 - 1.8 m maximum diameter) placed in the nearshore zone in approximately 4 to 6 m mean water depths. The mitigation reef was constructed in six discrete areas between FDEP survey monuments R-101 and R-125 during August and September 2003.

The anticipated burial of natural hardbottom initiated a comparative evaluation between natural hardbottom areas and the mitigation reef. The monitoring program intended to measure the recovery potential that mitigative reefs provide to compensate for the anticipated burial of natural hardbottom.

Methods

Benthic assessment

Twenty-seven fixed 30-meter transects were monitored on the artificial reef and twenty-six fixed 30-meter transects were monitored on the natural hardbottom for comparison. Monitoring took place at six discrete sampling events between May 2004 and September

2008, and are referred to as the 9-, 12-, 18-, 24-, 36-, and 60-month post-mitigation monitoring events.

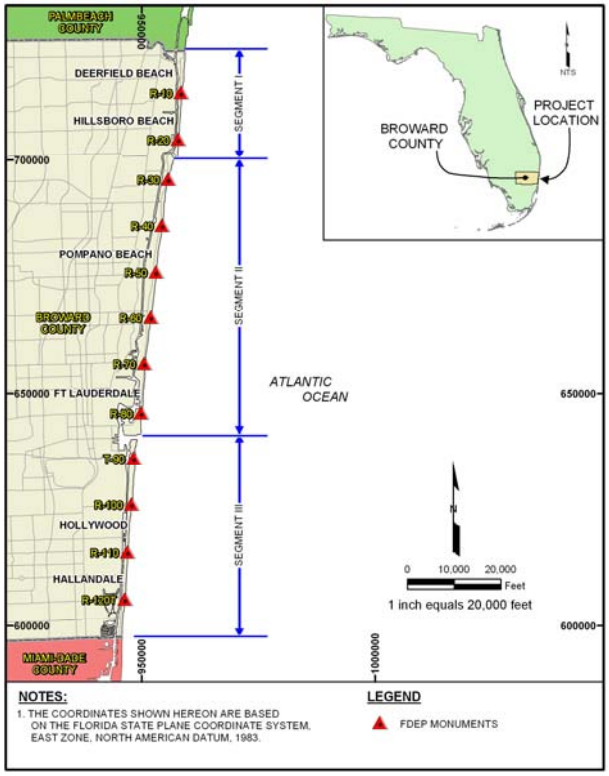

Figure 1: Location map of Broward County Segment III Shore Protection Project.

Benthic communities were evaluated using the Coastal Planning & Engineering, Inc. Benthic Environmental Assessment for Marginal Reef (BEAMR) method (Lybolt and Baron 2006) which uses percent cover as a proxy for abundance. BEAMR was conducted at each specified transect using 12 replicate 1.0-m^2 quadrats (1.0 m x 1.0 m) every 2.5 meters, starting at 0.0 m for a total of 12 m^2 planar area per transect. The 9-month post-mitigation BEAMR surveys were conducted using 0.25-m^2 quadrats (0.5 m x 0.5 m). The quadrat size was changed to 1.0-m^2 in order to align these data with the Shore Protection Project beach construction compliance *in situ* monitoring, a parallel project. All subsequent surveys used the 1.0-m^2 quadrats.

Statistical analysis

PRIMER v6 non-parametric statistical package (Clarke and Warwick 2001) was used to compare the benthic assemblage between the artificial reef and the adjacent natural hardbottom using transect-level average percent cover for functional groups and macroalgae genera. The data were standardized by total and transformed as appropriate. Similarity Percentages (SIMPER) were applied to determine which taxa contributed to the average dissimilarity ($\bar{\delta}$) between substrate types (artificial vs. natural). A Bray-Curtis similarity matrix was applied to the transformed dataset to generate multi-dimensional scaling (MDS) ordinations and analysis of similarity (ANOSIM) routines in order to determine changes in the level of similarity between the artificial reef and natural hardbottom over time.

Results

Functional Groups

Natural Hardbottom vs. Artificial Reef

Sediment is one of the functional groups sampled for in BEAMR but was removed from the dataset in order to compare the biotic benthic community between the two reef types. Table 1 presents percent contribution of each taxa to the average dissimilarity between the artificial and natural reefs with a cutoff of 70%. Macroalgae, zoanthid, and turf algae cover generally dominated the contribution to the average dissimilarity. By 60-month post-mitigation, the dissimilarity decreased to 25.54% between the reef types.

Table 1: The percent contribution of specific functional groups to the average dissimilarity between the artificial reef and natural hardbottom.

Functional Group	Percent contribution of the i^{th} taxa to the average dissimilarity b/n the artificial reef and natural hardbottom					
	9-Mo	12-Mo	18-Mo	24-Mo	36-Mo	60-Mo
Macroalgae	15.90%	11.70%	11.71%	7.38%	11.59%	12.45%
Zoanthid	11.51%	14.04%	14.12%	14.38%	11.90%	13.00%
Turf algae	13.85%	8.97%		8.46%	12.32%	
Sponge	8.48%		5.97%		9.61%	11.99%
BHS	7.78%	10.90%	11.43%	21.77%	5.66%	
Octocoral		11.10%	9.25%	9.67%	11.64%	7.32%
Wormrock			11.58%	9.72%		5.87%
Bryozoan	10.19%					
Stony coral	7.44%	8.84%	8.38%		4.43%	
Encr red algae		6.93%				
Tunicate					5.14%	6.16%
Bivalve						8.27%
Hydroid						5.58%
Average dissimilarity ($\bar{\delta}$)	33.34%	34.27%	30.97%	41.88%	33.14%	25.54%

*BHS is bare hard substrate

Abiotic and floral groups were removed from the dataset to compare the faunal functional group assemblage between the artificial reef and natural hardbottom at each discrete monitoring event. MDS ordinations were generated and SIMPER and ANOSIM routines were applied to determine the average dissimilarity and the degree of similarity (R-value) between the two substrate types (Fig. 2).

Artificial Reef over Time

The biotic benthic community of the artificial reef was plotted in an MDS ordination to display change in community composition over time. Fig. 3 indicates

progression towards a stabilizing community as the most recent datapoints cluster together. A post-hoc ANOSIM supports this hypothesis, where the lowest R-values are found between 18 and 60 months post-mitigation (Table 2).

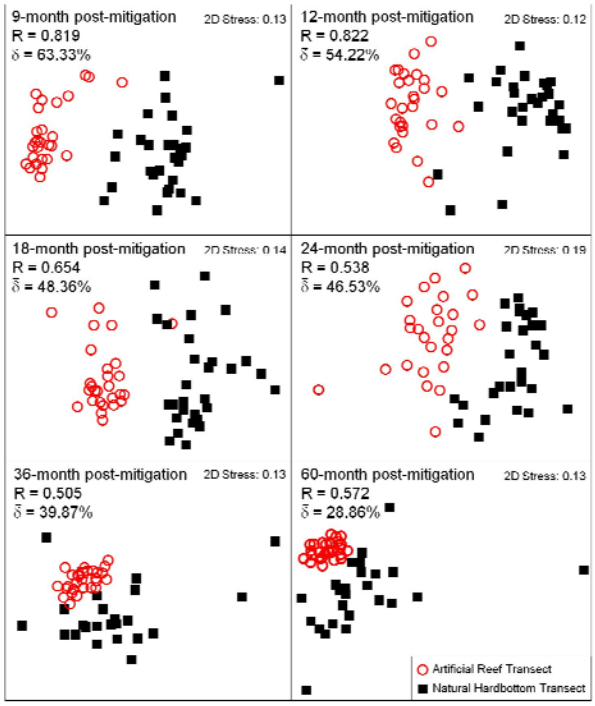

Figure 2: MDS plots of the artificial reef and natural hardbottom benthic faunal assemblages with associated ANOSIM and SIMPER results (R and $\bar{\delta}$).

Macroalgae

Macroalgal recruitment and community development was of particular concern on the artificial reef due to the anticipated loss of turtle foraging habitat from hardbottom burial. Makowski et al (2006) and Wershoven and Wershoven (1992) identified 12 genera of macroalgae that are common to the diet of juvenile green sea turtles (*Chelonia mydas*) in Palm Beach and Broward Counties. Six of the seven 'preferred' macroalgae that are found on the natural hardbottom were identified on the artificial reef.

In total thirty-four genera of macroalgae were identified on the artificial and natural substrates. Thirty-two were found on the natural hardbottom and 25 were identified on the artificial reef. Fig. 4 presents the average percent cover of macroalgae on the artificial and natural substrates as well as the average dissimilarity (determined from SIMPER) between the two substrate types at each monitoring event.

Macroalgae cover increased steadily with an associated decrease in dissimilarity, until a sharp decline after the 18-month monitoring event. This is likely a result of the intense hurricane activity experienced in south Florida in 2005, which may have caused scouring on both substrate types. Macroalgae cover recovered and continued to increase on the artificial reef by 36 months but remained relatively low on the natural hardbottom. As cover on both substrate types increased, dissimilarity decreased and vice-versa.

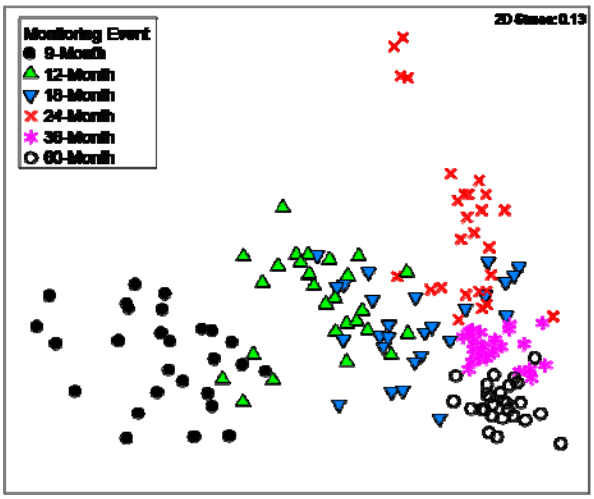

Figure 3: MDS plot of the biotic benthic community on the artificial reef over time.

Table 2: R-values from ANOSIM comparing the similarity in the biotic benthic community on the artificial reef over time.

ANOSIM R-value	9-Mo	12-Mo	18-Mo	24-Mo	36-Mo
12-Mo	0.688				
18-Mo	0.954	0.448			
24-Mo	0.981	0.731	0.520		
36-Mo	0.999	0.872	0.537	0.636	
60-Mo	0.999	0.928	0.795	0.733	0.670

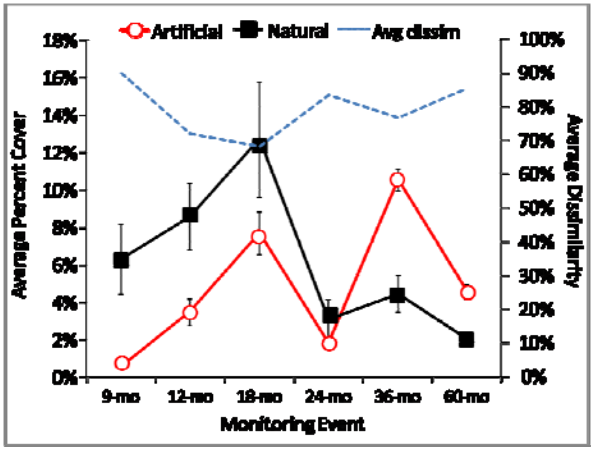

Figure 4: Average percent cover of macroalgae and average dissimilarity between the artificial and natural substrates over time.

Discussion

Connel and Keough (1985) surmise that assemblages on artificial reefs may through time converge towards

an epibiotic assemblage on natural substrata. This study set out to determine if the benthic assemblage on the Broward County artificial reef is approaching habitat equivalency, or at least similarity, to the surrounding natural hardbottom using a long-term monitoring program.

The benthic community between the two reef types proved to increase in similarity but remained functionally distinct 5 years post-deployment of the artificial reef. The dissimilarity between the macroalgal community on the artificial and natural substrates fluctuated over time displaying no obvious trend except that the factors which influence macroalgae cover appear to affect both substrates concurrently.

The dynamic assemblages that are well known on natural hardbottom off the coast of Broward County may be markedly different from the developing assemblages found on the mitigative substrate due, in large part, to variations in the biological and physical environment created by the boulders. Structural differences between artificial and natural substrates can ultimately lead to two distinct reef communities (Perkol-Finkel and Benayahu 2007). The high relief of the artificial reef boulders in Broward County will likely be the limiting factor in reaching habitat equivalency to the surrounding natural hardbottom.

Acknowledgement
We would like to thank the Marine Science and Biological Research Department at Coastal Planning & Engineering, Inc. for the monitoring program development, data collection, research and analytical support. We would also like to thank Broward County Environmental Protection Department for their participation, as this data was collected as part of the ongoing biological monitoring program for the Broward County SPP.

2) Current Address: Marine Research Centre, H White Waves, Male', Republic of Maldives

Abstract. Established on January 15, 2003, the St. Croix East End Marine Park (STXEEMP) is the U.S. Virgin Islands' first marine park and represents the culmination of three years of collaboration between the federal and local government, non-governmental organizations and other stakeholders. The STXEEMP is on the eastern end of St. Croix extending from the high tide boundary to the three nautical mile territorial waters limit. The park was designed to protect the largest island barrier reef system in the Caribbean and to promote sustainability of coral reefs, seagrass beds and mangrove habitats and to preserve significant natural areas for the benefit of future generations. A park managed monitoring program designed to collect scientific information to assist in the wise management of these habitats and species to ensure that these marine resources are available in the future has yet to be implemented. The park's education and outreach program's goals are to facilitate environmental awareness opportunities for the community, encourage a sense of user stewardship regarding the marine environment and promote the awareness of and support for the park. In October 2005, the park's headquarters was finally established on a historic plantation site adjacent to the park and an interpretive program implemented.

Key words: Marine Protected Area, Caribbean, regulations

Introduction

The St. Croix East End Marine Park (STXEEMP) is located at the east end of St. Croix in the United States Virgin Islands (VI) (Fig. 1). The VI consists of three large islands – St. Croix, St. Thomas, and St. John and over 50 small islets and cays. Located at the eastern end of the Greater Antilles, the VI is home to over 120,000 people and hosts over 1.3 million visitors annually. St. Croix is the largest island with a land mass of >218 km^2.

The park surrounds the east end of St. Croix from the high tide mark out to three nautical miles. The northwest boundary starts at Chenay Bay ($17^o45'39"N$; $64^o40'5"W$) and ends at the south west boundary at Great Pond Bay ($17^o42'51"N$, $64^o39'52"W$) encompassing an area of approximately 60 $miles^2$ (155 km^2) (Fig. 1). The shoreline that borders the park is approximately 17 miles (27 km) long. The park is within the jurisdiction of the VI territorial government as it lies within the three nautical mile territorial boundary. The Buck Island Reef National Monument is juxtaposed to the park and is under the jurisdiction of the U.S. Federal government. The land bordering the park is within the Coastal Zone First Tier and any development activity is subject to approval by the VI Coastal Zone Commission.

In 1960, the Department of Interior completed a study for the Governor of the VI that recommended that the east end of St. Croix be designated as a nature preserve. A series of similar designations have been made in the past 40 years for the land and waters of the east end of St. Croix, including:

- Designation as an Area of Particular Concern (APC) – 1979
- Designation as an Area for Preservation and Restoration (Teytaud 1980)
- Nomination as a Significant Natural Area (Teytaud 1980)
- Candidate for park within VI Territorial Park System plan (Alexander 1981)
- Nomination as a candidate for National Marine Sanctuary status- 1982
- Recommended as a multi-purpose park within proposed Territorial Park System (Island Resources Foundation 1991)

Management Approaches

Multi use design

In order to establish a functional multi use park a management plan was devised with four managed areas: Recreation, Turtle Wildlife Preserve, No Take and Open Fishing (Fig 1). The Recreation Areas include 2.8% of the park and are designated for snorkeling, diving, recreational fishing, bait fishing and boating while preserving resources. The Turtle Wildlife Preserve Area covers 7.0% of park waters and protects turtle nesting beaches for Green, Hawks-

bill and Leatherback turtles. The No Take Areas only encompass 8.6% of the park and are designed to protect spawning, nursery, and residence habitat for various species. The Open Fishing Areas comprise 81.6% of the park and presently provide little additional protection than exists in other territorial waters. Existing territorial restrictions govern the use of these areas; the only marine park restriction is the prohibition of the removal of coral or live rock in these areas.

No Take Areas were designed to encompass large, contiguous diverse habitats. They are intended:

- to provide natural spawning, nursery, and permanent residence areas for the replenishment and genetic protection of marine life, and
- to protect and preserve all habitats and species; particularly those not protected by fisheries management regulations.

This zone was intended to protect areas that represent the full range of diversity of resources and habitats found throughout the park.

Turtle Wildlife Preserve Areas were established:

- to minimize disturbance to sensitive wildlife populations and their habitats,
- to ensure protection and preservation of wildlife resources in the park.

This designation will be applied to the primary turtle nesting beaches and near shore resting areas. Regulations governing access are designed to protect the endangered turtles and their habitat, while providing opportunities for public use.

Recreational Areas are designed to provide areas for snorkeling, diving, and boating while prohibiting any activities that would compromise the recreational values for which the area may be designated. Restricted activities will be defined in future public input meetings. Specified recreational opportunities may be protected, enhanced or restricted, while preserving basic resource values of the area. No other uses are specifically restricted with the exception of general shipping.

Open Fishing Areas are areas in which there are no additional restrictions on fishing, boating, and diving activities. These areas are governed by all the rules and regulations pertaining to commercial and recreational fishing in the VI Code. These areas are designated to monitor and evaluate the effects of resource zoning in the park. Trawling and general shipping are prohibited, as well as those activities inconsistent with the park's long-term conservation (*e.g.*, mining and oil drilling).

Rules and regulations

Although the STXEEMP was established in January 2003, the enabling documents establishing the Rules and Regulations (R&R) were not signed by Governor John P deJongh until September 2007. The purpose of the R&R was to provide specific rules to protect park resources from both direct and indirect threats. These regulations focus on habitat protection, reducing threats to water quality, and minimizing human impact to delicate resources. The park regulations have been established to complement those in existing management areas, including Buck Island National Monument and Green Cay National Wildlife Refuge.

The following activities are prohibited park wide:

- removing, injuring, or possessing coral or live rock,
- discharging or depositing trash or other pollutants,
- dredging, drilling, prop dredging, or otherwise altering the seabed, or placing or abandoning any structure on the seabed,
- operating a vessel in such a manner as to strike or otherwise injure coral, seagrass, or other organisms attached to the seabed, or cause prop scarring,
- having a vessel anchored in a manner other than the use of a reef mooring buoy,
- operating a vessel at more than idle sped/no wake within 100 yards of park vessels and navigational aids marking reefs,
- operating a vessel at more than idle speed/no wake within 100 feet of a diver down flag,
- diving or snorkeling without a dive flag,
- operating a vessel in such a manner which endangers life, limb, marine resource or property,
- releasing exotic species,
- damaging or removing markers, mooring buoys, scientific equipment, boundary buoys, and trap buoys,
- moving, removing, injuring, or possessing historical resources,
- taking or possessing protected wildlife,
- using or possessing explosives, and
- using firearms.

In addition to the park wide rules, the following activities are prohibited in the No Take Area:

- discharging any matter except cooling or engine exhaust,
- fishing by any means, removing, harvesting or possessing any marine life,
- touching standing on living or dead coral, and
- anchoring on living or dead coral, or any attached organism.

In addition to the park wide rules, the following public access restrictions in the Wildlife Preservation Area include:

- idle speed only - no wake,
- no access buffer,

- no outboard motors, and
- establishment of limited closure periods.

The R&R do not go into effect until 30 days after public notices have been distributed stating that the park's boundary markers have been deployed. Although funds have been available for several funding cycles and the previous Department of Planning and Natural Resources (DPNR) Commissioner signed a contract to deploy the boundary bouys, the contract has lapsed. In August 2008, the ex Commissioner was sentenced to a prison term of seven years on corruption charges and misuse of Coastal Zone Management funds. As of July 2008, there was no contract for deploying the boundary markers and thereby turning the existing paper park rules and regulation into a legally enforceable code.

Enforcement strategies

The primary law enforcement objective in the park is to achieve resource protection by gaining compliance with the Park regulations and other Federal and Territorial statutes that apply within the STXEEMP. An enforcement program is one of the tools available to managers of marine protected areas, and is considered by the initial planners to be a Best Management Practice. They thought that such a program could compliment other management programs, such as research and education, and lead to increased levels of success. Of course successful enforcement would require resource managers to commit to enforcement programs that are properly supervised and funded. In the first five years of the park's existence this has not happened. The entire idea may be unrealistic in the near future given the existing political conflicts in managing the park.

The enforcement philosophy should be that preventive enforcement is best achieved by maintaining sufficient patrol presence within the Park to deter violations and by preventing, through education, inadvertent violations of the law. Successful enforcement relies on frequent water patrols, and routine vessel boardings and inspections. Water patrols would ensure that park users were familiar with park regulations, deter willful or inadvertent violations of the law, and provide quick response to violations and/or emergencies.

The success of park enforcement will depend on how well the enforcement entities on St. Croix are coordinated. Because of limited resources at the Federal, Territorial and park level, enforcement assets must be targeted and used in an efficient and directed effort to achieve compliance with existing and proposed regulations. The coordination of enforcement assets will be an integral component of the management of the park. Interagency agreements among other enforcement entities on St. Croix should be developed, including the National Park Service, US Fish and Wildlife Service, US Coast Guard, VI Department of Planning and Natural Resources (Enforcement Division) and the VI Police Dept. All of this is predicated on having senior managers in DPNR who are knowledgeable about environmental management and have the political interest and stamina to advance the park.

Monitoring and measuring success

Site evaluation and monitoring should be a continuous process, with regular reporting intervals and a formal evaluation mechanism. All monitoring plans should include acceptable limits of change. A monitoring program should be able to provide managers with fundamental information with which to make decisions, and would facilitate a flexible approach, as well as a responsive management system. A comprehensive review by a scientifically qualified review team, performed on at least a bi-annual basis, would help to ensure that implementation was occurring as planned. Site monitoring activities should have been guided by the following objectives:

- Establish a baseline within the respective use-zones within the park, thus providing a means for measuring success in the future,
- Collect park utilization data to be part of a social and cultural analyses and used to modify and enhance park regulations and activities,
- Collect biological data that are representative of the status and health of marine organisms and their respective habitats, and
- Collect fisheries data that quantify fishing trends (*i.e.*, fishing methods, species caught, amount caught, etc.) within park boundaries.

The park has yet to establish a baseline monitoring program of biophysical parameters necessary to assess climate change (Quinn & Kojis 1995) or a baseline survey of fauna and flora. Instead of hiring and training technically competent personnel the park has relied on non government organizations, the local university and federal agencies to gather data in the shallow water communities. Surveys in the deep water habitats that require equipment and skills beyond the capacity of the territorial government have not been conducted and would be an appropriate task for federal agencies.

The use of non VI government agencies is clearly an easy approach, but will later be subject to closer scrutiny as the validity of park management issues come under question. NGOs are not objective local stakeholders, but rather entities with a political agenda to advance environmental conservation supported by an off island constituency. Likewise federal agencies are viewed with suspicion and by some islanders who view federal involvement in island

resource management as meddling by outsiders. One has to wonder why support for capacity building and empowerment of territorial government agencies was not given greater priority. Certainly the objectivity of the data collected by NGOs should be subject to scrutiny. It is a rather politically dubious situation when the park bases it scientific management on the findings of an organization with a clear bias. The evidence suggests that the funding agencies have little sensitivity to the political nature of marine resource utilization in St. Croix and the importance of the capacity building of objective professional standards in territorial government agencies.

Education and outreach

Throughout the planning process, the need for a comprehensive and effective educational program was emphasized. Activities such as public forums, printed materials, public events, school tours and an interpretive program will help to advance the community's awareness of the importance and activities in the park. In January 2008, the park's interpretive program commenced with weekly tours of the watershed adjacent to the park and fauna and flora tours to schools groups of Great Pond Bay. The tours were well attended by the public and the park received favorable TV and print publicity.

Park headquarters at Estate Great Pond (EGP)

The headquarters of the STXEEMP was relocated to a restored colonial building at EGP in October 2007, almost five years after the creation of the park. The cultural resources on EGP represent a historical chronology of over 600 years of changing land uses and human occupants. During the era of Danish sovereignty (1735-1917), the Great Pond area fell within the boundaries of different plantation grounds. Due to the constant change of property ownership and land uses, the Great Pond plantations were consolidated or sold separately from 1760-1916.

Estate Great Pond is a testimony to the history of agriculture on this southern section of St. Croix. The property presently consists of a late 18th century great house, remains of a factory, slave quarters, stable area or storage room, and other historical ruins. Cotton was planted during the initial development of the plantation in the 1770's because cotton grew well in a dry environment. The 18th century storage building west of the great house and north of the factory was where cotton was stored and processed.

By the late 1700's to the early 1800's, the estate was a sugar plantation with many owners. The only documented occupation after 1800 occurred in 1843 to 1845. However, no evidence has been found of post-emancipation use by renters and/or small holders. Although, it is possible that such marginal activity may have escaped the attention of the record keepers. By the early 1900's, the Great Pond area was a sugar plantation and used for grazing animals. In 1902, the Danish West Indies' Plantation Co. purchased EGP. The area was used as an agricultural experiment station for a short time.

When the Danish Virgin Islands colony was purchased in 1917 by the United States, the EGP was gradually subdivided. Sugar production on St. Croix began to fall again after the United States purchased the islands. By 1933, much of the sugar cane producing land on the island was abandoned and the lands reverted to cattle grazing. The division of rural land including the Great Pond area by end of the decade was 75% pastures, 15% cane and 10% bush land. By the 1960's, agriculture in the Great Pond area had ceased and only cattle grazing remained.

The EGP is also identified as a Pre-Columbian site. The site stretched for more than a half mile along the coast, but generally not further than a few hundred feet from the shoreline. The first excavations conducted at the Great Pond site found substantial artifacts dating to the Longford Stage (Saladoid, A.D. 300-700) and remains from the Richmond Stage (Ostionoid, A.D. 700 - 900).

The area is registered and listed in the National Register for Historical Places. According to archaeologists, the whole site possesses considerable historic archaeological findings, and therefore needs to be protected from unnecessary ground disturbances. The history of the area includes Africans, Europeans, and native North American Indians. Therefore, the Great Pond area is very significant to the people of the VI and visitors.

In the early 1970's, the Department of Conservation and Cultural Affairs recognized the need to provide recreational facilities and programs in the newly developing areas in the east end of St. Croix. In 1974, Governor Melvin H Evans, negotiated the land transfer and a charitable trust was created. The people of the Virgin Islands and its visitors received in perpetuity a valuable piece of seashore property with its historic buildings and artifacts.

In 1974, funds were appropriated for the VI Territorial Parks System. During this period plans were considered for the development of the EGP site into a park. Camp Arawak was allowed to utilize the area for a training school for youth. However, after Hurricane Georges in 1998, the Camp Arawak Program relocated to Christiansted. Afterwards other groups and individuals continued to use the area for overnight camping, picnics, fishing, swimming and natural history education. The second floor of the factory building of the EGP plantation is currently used as a business office and focal point for school and public natural history interpretive tours.

Future prospects

STXEEMP is the VIs' first territorial marine park and is the cornerstone to the proposed future territorial park system and possibly to a regional network of marine protected areas necessary for the best management and conservation of many commercial species (Kojis et al. 1995). It was established at a cost of over $1 million of US federal funds, $1 million territorial government matching funds and in kind support from NGOs worth over $0.5 million.

The park's purpose of managing the valuable marine resources on the east end of St. Croix still has not been realized. It is generally accepted that these natural and cultural resources should be preserved for residents and visitors. However, these resources need to be managed by a technically competent territorial agency managed by professionally managers dedicated to managing these resources for the people of the VI and it's visitors. It is imperative that these resources be managed in a cost effective manner with less dependency on federal assistance in a fair and impartial matter that guarantees the benefits are available for present and future generations.

Acknowledgement

I would like to gratefully acknowledge Department of Planning and Natural Resources Commissioner Robert S Mathes and Coastal Zone Management Director Janice Hodge for their support and encouragement. Without their efforts the park would not be where it is today. Financial support for the park is through National Oceanic Atmospheric Administration funding to the US Virgin Islands territorial government's Coastal Zone Management Program. Dana Wusinich-Mendez deserves particular recognition for her efforts to develop and provide support for the establishment and management of the park. Discussions with BL Kojis regarding the park's history and politics are gratefully acknowledged. Discussions with John Farchette III greatly assisted in developing the historical and cultural perspective of implementing the park. The support of the Tropical Discoveries Fund is gratefully acknowledged.

Abstract. Traditionally Marine Managed Areas (MMAs) have been established to achieve biodiversity conservation goals (e.g. protect endangered species, increase fish populations); yet increasingly social, economic and cultural objectives are being incorporated into MMA planning. To understand the effects on human communities from including socio-economic objectives in MMAs goals, a cross-site study was designed to examine the socioeconomic and governance effects of MMAs in four countries (Belize, Brazil, Fiji and Panama) as well as ecological factors influencing these outcomes. A socioeconomic and governance monitoring survey is being conducted in each of the MMA coastal communities to understand conditions prior to MMA establishment compared with current conditions. The analysis will assess the MMA effects on food security of coastal residents, livelihoods, human threats to the marine resources, and environmental awareness and knowledge as well as assess the governance effects, including impacts on management structures and strategies, stakeholder participation and representation, property rights and access to resources, management plan compliance by resource users. In addition, enabling factors for MMA effectiveness will be determined. The factors being examined include leadership and long term support of local government, participation by community and all those affected, shared benefits among participants, and alternative livelihoods that may be appropriate in decreasing resource use pressures within MMAs. This project within the Conservation International Marine Management Area Science Program, is a work in progress and demonstrates the application of monitoring and research to support improved understanding and adaptive management of coral reefs and related ecosystems.

Key words: governance, marine protected area, monitoring, socioeconomics.

Introduction

Marine managed areas[1] (MMAs) are used throughout the world to cope with human impacts on marine ecosystems by limiting unsustainable economic activities, reducing user conflicts, and promoting non-extractive uses such as recreation activities. Marine conservation efforts are recognized as working with over 75% of respondents in Caribbean and Southeast Asia acknowledging marine area conservation benefits (Loper et al. 2008). An understanding of socioeconomic and governance conditions is vital for effective implementation of MMAs.

Socioeconomic and governance monitoring is a critical tool with which coastal and ocean resource managers can determine the impact and effectiveness of their management programs. It does little good to understand the health of coral reef and other coastal resources without understanding how people are interacting with those resources or what those resources are worth to local communities. Lloret and Riera (2008) examined the evolution of human uses ini the marine environment of Cape Creus and emphasized the increasing socioeconomic importance of recreational activities in detriment to artisanal

[1] Marine managed area (MMA) and marine protected area (MPA) each have the same base definition, MPAs are primarily intended to protect or conserve marine life and habitat, and are therefore a subset of marine managed areas (MMAs), which are broader groups of named, discrete geographic areas along the coast that protect, conserve, or otherwise manage a variety of resources and uses, including living marine resources, cultural and historical resources, and recreational opportunities. Marine managed area classifications include state water quality protection area, state marine cultural preservation area, and state marine recreational management area (as defined in Fish and Game Code Section 2852. Source: http://www.dfg.ca.gov/mlpa/defs.asp)

fisheries. Apparent threshold levels of dependence on marine resources, material wealth, distance to markets and population, exist when considering customary forms of resource management (Cinner et al. 2007). On the sustainability of social-ecological systems, certain attributes of governance function in society to enhance the capacity to manage resilience in marine (Lobel et al. 2006). Given the paucity of socioeconomic and governance data available, there is an increasing demand globally from MMA managers, decision-makers, resource users, scientists and other stakeholders to understand the socioeconomic and governance conditions of MMAs.

Both government and non-government agencies, as well as other stakeholder groups, recognize that the dearth of existing data regarding the socio-economic and governance aspects of coastal and marine ecosystem management creates challenges for effective planning and implementation. This study will demonstrate the effects of MMAs on socioeconomic and governance conditions in the surrounding communities. In addition, this study will provide socioeconomic and governance information useful for determining how marine area management is contributing to community development, including poverty alleviation and equitable sharing of benefits. The synthesis analysis will contribute to marine conservation efforts at the site, regional and global levels, especially when integrated with the ecological monitoring results.

Methods

Figure 1 presents the coastal communities in the four countries where socioeconomic and governance monitoring is being conducted. These communities were selected for this study based on stakeholder consultation on access to MMAs and use patterns or dependence on marine ecosystems. These communities and corresponding MMAs are presented in Table 1.

Data collection is currently being undertaken. This involves literature review and primary data gathering. This was done as a collaborative endeavor among the participating local institutions and stakeholder groups. Surveyed respondents (n = 2736) were from a random sample (90 to 95% confidence) of MMA user groups within coastal communities.

The selection of the socioeconomic and governance variables was based on the MMAs' management objectives contained in their respective plans. The management objectives cover relevant socioeconomic and governance aspects. In addition, a series of community level multi-stakeholder consultations were undertaken to develop a consensus on identifying and selecting appropriate socioeconomic and governance indicators to measure these effects.

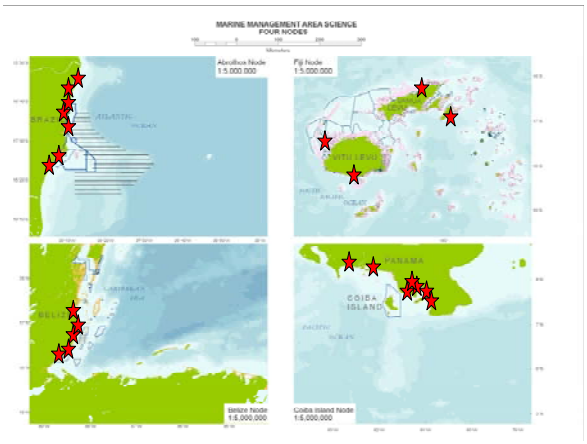

Figure 1: Location of coastal communities in the four nodes covered in this study. (counter clockwise, from top left map: (1) Abrolhos. Brazil; (2) Fiji; (3) Belize; and (4) Coiba, Panama.

Table 1: Socioeconomic effects of marine managed areas.

Country	Marine Managed Areas	Coastal communities
Belize	Lighthouse Reef, Laughing Bird Caye, South Water Marine Reserve, Sapodilla Cayes, Port Honduras Marine Reserve	Sarteneja , Chunox , Copper Bank, Dangriga, Hopkins, Sittee River, Seine Bight, Independence, Placencia, Monkey River, Punta Negra, Punta Gorda
Brazil	Albrolhos National Park, Corumbau Extractive Reserve, Cassaruba	Portu Seguro, Caraiva, Corumbau, Prado, Alcobaca, Caravelas, Nova Viscosa
Fiji	Navakavu, Waitabu, Navatu, Malolo	Waiqanake, Muaivusu, Namakala, Nabaka, Waitabu, Boumai, Lavena, Navatu, Solevu, Yaro
Panama	Coiba National Park	Pedregal, Remedios, Pixvae, Bahia Honda, Santa Catalina, Hicaco, Puerto Mutis, Leones Arriba, Gobernadora, Malena

In order to evaluate the socioeconomic impact of MMAs on individuals of specific user groups, baseline conditions prior to the establishment of MMAs were determined. Comparing the current conditions and trends against this baseline provided a basis for measuring the effect of MMAs. In the absence of existing baseline data, other benchmarks were identified.

Survey instruments were developed to measure effects on:

- Livelihood outcomes: Have the family improved economically? Have economic activities

diversified? Do households have more services available? Have the dependency on marine resource changed? Are there infrastructures changes?

- Perceptions on environmental problems: have community environmental concerns changed?
- Perceptions about and use of the MMA: are the restrictions imposed on access to resources perceived as harmful? Do communities perceive that they can take benefit from the MMA? Has knowledge about the MMA increased?
- Use of marine resources and economic activity: monthly family income, main source of income, membership in commercial organizations (coops, etc.), use of coastal resources, frequency of marine related activities, use of MMA, types of tourism activities done in the area
- Community organization and participation: are more people participating in community-based groups? Are more people participating in the MMA activities? Has the awareness of environmental/community projects increased?

In all four countries, the socioeconomic and governance monitoring sites are the same sites where ecological monitoring is being conducted. This is to ensure integration of the data for cross-disciplinary analysis of: (1) which ecological factors (e.g. productivity of extractive resources, habitat quality, ability to absorb waste, frequency of natural disturbances) affect socioeconomic outcomes (e.g. livelihoods); and (2) which socioeconomic (e.g. resource use patterns) or governance factors (e.g. stakeholder participation) affect ecological outcomes.

Preliminary Observations

Data gathering and analysis is underway in Belize, Brazil, Fiji and Panama with stakeholder consultation meetings conducted since March 2007 with local non-government organizations, MMA management bodies, and civil society groups including fishers' organizations, tour operators and tour guide associations. In addition, secondary data analysis (e.g., reports from government agencies, profiles of communities, etc.) is complete.

In Belize, fishing is not only an economic activity but a way of life, enhancing social and cultural values. More recently, the managers of protected areas have formed themselves into an association called the Association of Protected Areas Managers Organizations (APAMO). APAMO was organized to strengthen the Protected Areas Network in Belize. Through APAMO it is expected that protected areas management will evolve to focus more on a systems approach to conservation and sustainable management. Belize is a good example of co-management agreements that can be strengthened to cover key emerging issues such as stakeholder participation, conflict resolution, and recovery of investments. Creation and direct involvement of APAMO over activities in the MMA sites affect the immediate environment and ultimately, the environmental quality of the adjacent MMAs.

In Panama, the buffer zone of the Coiba National Park (CNP) has been experiencing several socio-economic and demographic changes over the past two decades. For example, fishermen in the area of Bahía Honda, Puerto Mutis, and Puerto Remedios mention having experienced a decrease in fishing productivity over the last few years which is attributed both to overfishing and to tighter regulations restricting fishing in areas of the CNP. This has implications on how some groups within communities are better positioned to take advantage of conservation benefits compared with others. There is a general positive sense about the park because it can strengthen the community (e.g.., diversifying the economy), however, there is some concern about the unequal distribution (e.g., permits to non-artisanal fishers) of benefits that may accrue only to the tourism sector.

Homogeneity of user groups across countries may have implications on the causality of effects of MMAs. Initial statistical runs for Belize and Panama show that there are significant differences in terms of four demographic parameters: household size, years of residence, age, education. In terms of perceptions of non-monetary benefits from MMAs, local communities in Belize consider marine ecosystems important, not only for extractive uses, but also for their non-use values (Figure 2).

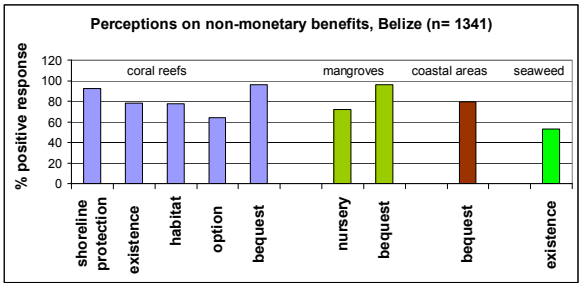

Figure 2: Perceptions on non-monetary benefits of marine managed areas in Belize.

Conclusion and Next Steps

Socio-economic and governance conditions provide the context within which coastal marine resources are managed. The values, perceptions and behaviors of local communities, key stakeholder groups and the policies developed and enforced by local and national authorities determine which areas are managed, the

extent to which they are managed and the level of compliance with management objectives. Changes in resource use and conservation patterns are therefore intricately linked to the overall political and socio-economic seascape.

Increasing poverty among coastal communities, literacy rates, historical or traditional resource use patterns, the increased cost of living, the rising cost of fuel and the annual threat of natural disasters, are just some of the variables that impact on how people interact with coastal marine ecosystems. In turn, people's interactions with coastal marine ecosystems determine the development of management strategies and the resources needed to conserve these ecosystems.

The level of conflict or compliance among user groups and with MMA management is often positively correlated with the lack of viable alternative livelihoods, resulting in communities engaging in illegal and destructive extraction activities. Hence, governance dimensions such as the type of MMA designation (e.g. ,national park, wildlife sanctuary etc.), the type of management structure (eg: government, non-government or community-based), the implementation of environmental education programs, the development of mechanisms to maintain stakeholder participation and involvement, and the effectiveness of the national legislation framework and the legal monitoring and enforcement system determine the relationship of people and marine ecosystems.

Managers of at last three of Belize's marine managed areas have begun to scientifically collect this type of data and use it in planning for more effective resource management. Because the integration of social science methodologies and approaches is groundbreaking for the conservation community, much learning regarding effective methods of study is taking place.

Data gathering in all four countries is expected to be completed in March 2009. Analysis will be completed by June 2009. The results from the synthesis of the socioeconomic and governance information from each of the countries, will provide information to: (1) establish a program of scientific monitoring of socioeconomic and governance processes for adaptive management; (2) measure the effectiveness of the MMAs in achieving its conservation goals; and (3) characterize and measure the effects of the MMA on ecological, socioeconomic and governance processes.

To ensure that the results from the socioeconomic and governance monitoring will feed into policy and decision-making, several products are being planned with relevant government and policy making bodies in each of the countries. For example, in Belize, the socio-economic and governance monitoring protocol is being developed for adoption by the Association of Protected Areas Management Organizations (APAMO).

The value of coral quality to SCUBA divers in Barbados

Abstract. The objective of this research is to estimate the economic value of coral reef quality related to SCUBA diving in Barbados. This value is derived using a stated preference survey of resident and tourist divers in Barbados conducted in 2007. In addition to a variety of demographic variables, divers were asked about their level of participation, expenditures related to travel and diving and encounters with specific species. Divers also identified characteristics of their most recent dive including price, crowding, fish diversity, encounters with marine turtles and coral reef quality and indicated their maximum willingness to pay for the dive. Coral quality was represented via a series of photographs representing a known range of coral cover. Hence, a quantifiable measure of coral cover is presented in a qualitative fashion that divers can understand. Results indicate that willingness to pay for increased coral quality varies with diver experience and the quality of their most recent dive. The results of this study can be used to inform management decisions regarding reef use and can aid in the development of policies aimed at maximizing the returns from diving while reducing the negative impacts of tourism activities.

Keywords: Coral quality, willingness-to-pay, marine turtles

Introduction

Barbados, like many tropical small island developing states, relies heavily on healthy coral reef ecosystems to maintain its shoreline and world famous white sand beaches, support nearshore artisanal fisheries and the tourism industry on which the GDP is now largely dependent (National Commission on Sustainable Development 2004). However, the very activities that depend on the reef, have taken their toll on reef condition, particularly those nearshore, and these reefs are now generally considered to be degraded through eutrophication, heavy use and over-harvesting (Government of Barbados 2002). This has compromised the resilience of Barbados' reefs to withstand additional external threats such as mass bleaching from elevated water temperatures associated with the global warming trend. The need for more effective conservation and management of the reef ecosystem in Barbados is clear, urgent and recognized by the Government (Coastal Zone Management Act 1998).

The purpose of this work is to understand the economic value of marine amenities in Barbados including coral reef quality, fish species diversity and marine turtles through econometric modeling of SCUBA divers' willingness to pay for dive quality characteristics. The analysis presented here represents a preliminary view of one component of a larger study examining the economic value of coastal and marine resources in the Caribbean.

Background and Literature Review

Coral reefs in the Caribbean provide a wide range of goods and services including seafood, numerous recreation opportunities, habitat, and coastal protection. Reefs also provide benefits indirectly via the jobs, income, and tax revenue generated via fisheries and marine tourism, and support human lives and livelihoods through the provision of food and materials, nutrient cycling, waste processing, and other essential goods and services. Coral reefs also have value in terms of their historic, cultural, medicinal and ecological significance.

The economic value of coral reef ecosystems is widely recognized as significant, receiving considerable attention in the popular press and academic literature in the past two decades. Numerous studies have used economic valuation methods to estimate willingness to pay for coral reef quality and the costs associated with coral reef degradation. Cesar et al. (2003) provide estimates of the value of coral reefs throughout the world, while Cesar (2000) and Gustavson and Huber (2000) provide summaries of the coral reef valuation

literature. Applications in the Caribbean include Dixon et al (1993), Spash (2000) and Parsons and Thur (2007). Brander et al. (2006) provide a meta-analysis of the recreational value of coral reefs from the literature through 2006.

Despite this attention to and recognition of value, coral reefs throughout the world continue to suffer from over-use and degradation. In the Caribbean, NOAA estimates that only 25 percent of reefs are in good health (Waddell and Clarke 2008). That the source of such significant value continues to be degraded is in large part due to the open-access nature of most reef ecosystems coupled with the failure of markets to properly allocate these resources to their highest valued use or provide proper incentives for conservation. Understanding how and why society values coral reef ecosystems can help alleviate the dearth of conservation-based management by calling attention to the degree to which reefs are undervalued and highlighting differences between potential and actual economic benefits derived from reefs. As is pointed out in Brander et al. (2006), coral reef values associated with recreation vary significantly across location and type of use, hence it is important from a policy perspective to have estimates of localized value.

Data

From June 2007 to April 2008, SCUBA divers were interviewed at dive shops in Barbados at the conclusion of their dives. In order to prevent bias associated with choice-based, on-site sampling, the distribution of surveys was matched with the exogenously determined distribution of actual divers across time and dive shop locations. In addition to a host of demographic information, divers described their most recent dive in terms of quantitative measures of fish species encountered, price paid, on-site crowding, marine turtles viewed, quality of coral cover viewed (via photo representation), and maximum willingness to pay for the dive. Divers also described their perceptions of dive quality using a series of five-point Likert scale ratings for water quality, amount of living coral on reefs, on-site crowding, level of supervision and amount and diversity of fish species encountered.

Nearly 70 percent of the 114 divers interviewed were male. The average age of divers in our sample was 38 years. Most divers in our sample were highly educated. Approximately 50 percent of the divers interviewed were visiting Barbados for the first time while only 13 percent were visiting the Caribbean for the first time. Over 57 percent of divers interviewed stated that they took vacations for the purpose of SCUBA diving. Divers in our sample have logged an average of 46 dives in the Caribbean over their lifetimes and had been diving for an average of seven years. Our sample of divers therefore has a varying degree of dive experience, Caribbean diving and general familiarity with the Caribbean.

While in Barbados, these individuals participated in numerous other recreations including beach going (79 percent), swimming (71 percent), swimming with turtles (26 percent), snorkeling from shore (41 percent), snorkeling from a boat (25 percent), sailing (19 percent), motor boating (17 percent), jet skiing (12 percent) and waterskiing (10 percent). Divers paid an average of US $104 for their 2-tank dive, had an average stated maximum willingness to pay of US $163, and expressed a high level of overall satisfaction with their dives in Barbados.

Methods

In order to estimate diver willingness to pay for coral reef quality, we regress stated maximum willingness to pay on dive quality variables, including a variable representing coral cover. This variable was acquired by showing divers four pictures of coral reefs and asking them which picture best represented the coral cover they encountered on their dive. These pictures were of reefs in Barbados where actual coral cover has been measured; actual coral cover ranged between five and 35 percent. Using this simple method however, proved ineffective as the quantitative measure of coral cover was not a significant determinant of willingness to pay. Examination of the data revealed the cause of this seemingly counterintuitive result: experienced divers viewed relatively high coral cover as poor while inexperienced divers viewed relatively low coral cover as good. That is, similar to results found elsewhere in the literature (e.g. Dearden et al. 2006), perceptions of coral quality varied greatly according to diver characteristics, including experience, number of visits to the Caribbean and participation in diving clubs and marine conservation organizations.

To account for variation in diver experience and other individual characteristics that may affect quality perceptions, we employ a two-stage econometric estimation of willingness to pay for coral cover. In the first stage, we regress divers stated satisfaction with coral cover (five point scale) as a function of actual coral cover viewed (measured coral cover in chosen photo representation) while controlling for experience and a host of individual and dive characteristics. Because the objective of this first stage of the estimation is to form a useful and accurate proxy for satisfaction with coral cover while controlling for diver characteristics, we are less interested in interpreting the coefficients from this model than in using the fitted values in our estimation of willingness to pay in the second stage. As such, we leave

statistically insignificant variables in the first stage model, noting that all variables in the model contribute to fit, and that the lack of individual coefficient significance may simply be the result of multicollinearity. In the second stage, we use the fitted values of satisfaction from the first stage as an independent variable in the estimation of maximum willingness to pay. Willingness to pay for quantitative improvements in coral quality can then be estimated by incorporating a hypothetical change in coral cover into the first stage (satisfaction) model and then adjusting the resulting fitted value in the second stage (willingness to pay) model.

Results

Results from the first stage (satisfaction with coral cover) model are shown in Table 1. When controlling for dive and diver experience variables, perceptions of coral quality are positively and significantly related to actual amount of coral cover viewed. Notably, divers visiting Barbados and the Caribbean for the first time, who were more satisfied with the dive overall, had a lower level of dive certification, and belonged to dive clubs, had better perceptions of coral quality. Males and divers who viewed Barbados diving as worse than most places where they have dived, tended to view coral quality as less favorable. Importantly for our purposes, the actual level of coral cover viewed is a positive and highly significant determinant of diver rating of coral quality while controlling for these other variables.

Table 1: Parameter Estimates Satisfaction with Coral Model

*** significant at 1% level, ** significant at 5% level, * significant at 10% level

The coefficients shown in Table 1 were used to generate fitted values of coral quality rating for each diver in the sample. These fitted values were then used as an independent variable along with the number of marine turtles viewed, the level of on-site crowding (number of other divers at the dive site), number of fish species encountered, and income, in a model of willingness to pay. These results are shown in Table 2. Divers' maximum willingness to pay is positively and significantly related to their perceptions of coral quality (modeled in stage 1), and the number of turtles encountered. On-site crowding significantly decreases willingness to pay. The relatively low goodness-of-fit in the second stage estimation is not unexpected given the small sample size and small number of explanatory variables included in the model, and is consistent with other estimates of willingness to pay in the literature (Asafu-Adjayea and Tapsuwan, 2008, for example).

Table 2: Parameter Estimates Willingness to Pay Model

Variable	Coefficient	P-value
Intercept	97.22*	0.08
Predicted value of coral quality rating (1st stage)	30.60***	0.01

Income	-0.0003	0.20
R^2 = 0. 20		

*** significant at 1% level, ** significant at 5% level, * significant at 10% level

Conclusion

In order to use these results to approximate willingness to pay for improvements in coral cover, we work through both stages of the modeling effort. For example, a 10-percent improvement in coral cover would result in a 0.2 increase in the predicted value of coral quality rating. When incorporated into the willingness to pay model, this results in willingness to pay increasing by approximately US $6.12. Hence, our results suggest that divers are willing to pay an additional US $6.12 per two-tank dive for a 10-percent improvement in coral cover in Barbados. Other notable results include divers' willing to pay US$10.35 per dive per additional marine turtle viewed, and US $5.17 per dive to avoid sharing dive boat and dive site with an additional diver.

Between 30,000 and 50,000 divers visit Barbados each year. If each diver participates in only one dive per visit to Barbados, additional economic value from dive tourism from a 10 percent increase in coral cover at dive sites could be as high as US$306,000. This estimate is most likely a lower bound on the true value to divers of such an improvement, as this estimate assumes the number of divers remains constant following an improvement in coral quality

and assumes each diver dives only once per visit. Coupling this result with divers' willingness to pay to avoid crowded sites would suggest that managing and restricting use at dive sites would both improve coral quality and economic gains.

Coral reefs in Barbados and throughout the Caribbean provide a significant source of economic value. Yet, coral reefs are declining in quality and may not be given due attention in policy formation and land use decisions. This work has shown that significant economic gains can be realized through efforts to improve coral quality.

Indonesia

Abstract. In 1998, the Indonesian government launched the Coral Reef Rehabilitation and Management Program (COREMAP) with the objective to enhance the health of coral reefs and to improve the welfare of coastal communities depending on coral reefs. The first National Policy, strategy and action plan was established in 2001 and implemented in 15 districts of 7 provinces. Scientific monitoring of coral reefs and socio-economic condition of dependent surrounding communities were carried out. Results indicated an improving trend in terms of live coral cover. Scientific results will be translated into popular articles in simple language which can be easily understood by all levels of stakeholders to enhance understanding of the importance of coral reefs. Components of community awareness and community control produced the most significant impact by reducing rates of degradation. Handing over management rights and control to local community stakeholders have proven efficient by increasing fisheries yield and community income. Television media and the involvement of community leaders proved the most efficient awareness media. Involvement of government officials in the awareness campaign activities has increased their appreciation of the importance of coral reefs for the people.

Key words : Coral Reef , Lessons Learned, Management

Introduction

Indonesia is the largest archipelagic country in the world (5000 km long, 2000 km wide) composed of 18,110 islands with a coastline of 108,920 km. Two shallow seas (the Sunda shelf in the west and the Sahul shelf in the east) are separated by a deep ocean that has existed since the Eocene (Tomascik et al, 1997). The Sulawesi, Flores and Banda Seas never dried up, in contrast to the Sunda and Sahul shelves, providing a chance for the marine biota to evolve continuously. Thus the waters surrounding the Sulawesi and Banda Seas are now one of the centers of biodiversity and Indonesia contains about 14 % of the world's reefs which are distributed unevenly from Sabang to Merauke with the highest concentration around Sulawesi and Banda seas.

More than 5 million Indonesian citizens depend on shallow water fisheries. Most of them are traditional fishermen who live at a subsistence level and depend fully on coral reefs resources. Despite this significant dependency, coral reefs in Indonesia are under serious threat from destructive fishing, bleaching events and pollution.

Aware of the importance of coral reefs to Indonesian society and the livelihoods of millions of coastal dwellers , and that reefs in Indonesia are under serious threat, the Indonesian government introduced a policy, strategy and action plan to improve the management of coral reef ecosystems. This paper tries to share the experience and the learning process to manage coral reefs in a developing country like Indonesia, starting from drafting the policy, strategy and action plan and its application process.

National Policy, Strategy and Action Plan

Drafting of the plan involved stakeholders at national level (academics, government officials, NGOs).as well as from all over Indonesia. After due consideration of inputs at national and local levels, a National Policy, Strategy and Action Plan was finally agreed upon, with the main objective of managing the coral reef ecosystems based on the balance between conservation and utilization. This plan was to be designed and implemented in an integrated and synergistic manner by the central and regional governments, civil societies, private sectors, higher education institutions and non government organizations. This National Policy, Strategy and Action Plan (NSPA) comprised 7 policies, 9 strategies and 34 action plans. Better known as "Coral Reef Rehabilitation and Management Program", it is sub-divided into three execution phases (initiation phase of 3 years, acceleration phase of 6 years and institutionalization phase of 6 years; COREMAP

LIPI 2001). The Action Plan of this program has five components: community awareness and education, control and surveillance, research and monitoring, community-based management, and institutional strengthening.

The COREMAP program was implemented in 7 Provinces (15 Districts) since 1998. The NPSA was made acceptable to all concerned and a legal basis for coral reef management was established. After much advocacy ranging from local communities to members of parliaments and the President, Constitution No. 27 of 2007 was decreed by the State Minister of Marine Affairs and Fisheries.

Research and monitoring included an education and training program as well as the establishment of an Information and Training Center (CRITC) at which 727 trainees (512 men and 215 women) were trained. Monitoring results of reefs appear to show no significant declines in reef quality (Table 1, Figs. 1 and 2). Coral reefs distribution was mapped using Landsat TM, resulting in imagery of ~19,500 km^2. 590 coral species in 82 genera or about 80 % of the world's total coral fauna (Fig. 3) were found.

Table 1. Status of Coral Reef Condition based on Percentage live Coral Cover from 77 areas and 908 stations (over what time frame?) [change commas to decimal points in % cover)

Location	Stations	Excellent	Good	Fair	Poor
West	362	5.5	27.1	33.9	33.4
Central	274	5.1	30.3	44.9	19.7
East	272	5.9	17.3	34.2	42.6
Total	908	5.5	25.1	37.3	32.1

Utilization pattern of coral reefs in Indonesia may be differentiated into three categories, (i) fishers who utilize coral reefs at one place for a certain time before moving on to other sites; (ii) fishing groups who use coral reefs at a fixed locality only; and (iii) those who fish periodically far away from their home. Relocation was motivated by the destruction and decrease in productivity of coral reef resources. This migrant fishing includes moving the entire family from one site to the next over a period of years. The migration cycle starting from the search for new locality rich in fish resources, followed by moving the whole family and developing a new settlement until the depletion of the resources and starting over again extends over some 50–60 years. Annual average population growth rate in coastal villages is 2.24% and migrant ratio 10-50%. (Kramer and Simanjuntak, 2000). Roaming fishermen move among islands during trips taking 3 – 6 months. This group has the highest potential for reef destruction due to absence of sense of ownership and emotional attachment to the location of exploitation and consists often of Bajo, Bugis and Madura clans who travel the entire Indonesian waters (Figure 4). Improved community awareness and provision of alternate incomes were identified as key prerequisites to alter destructive behavior and the program had some successes.

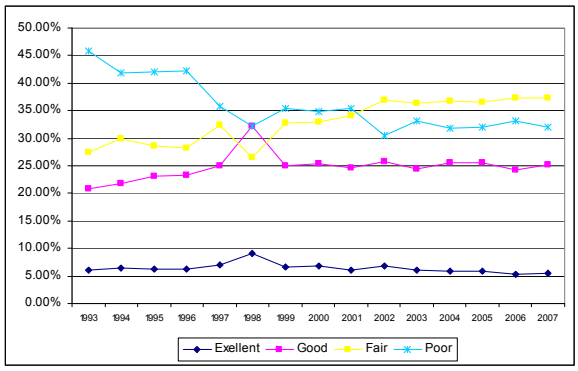

Figure 1. Trend of Coral Reef Condition (1993 – 2007)

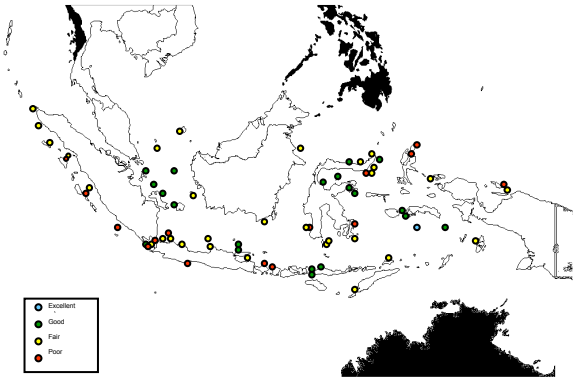

Figure 2. Coral Reef Condition in Indonesia [legend impossible to read—please fix figure]

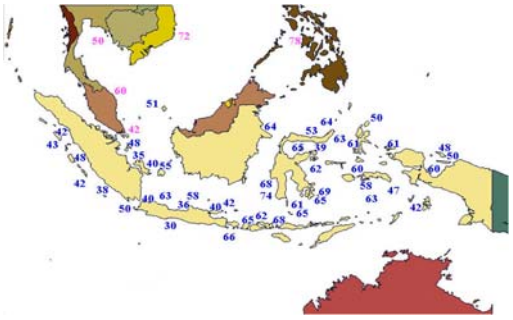

Figure 3. The Distribution of Coral genera in Indonesia.

Rivalry between the local institutions and minimal knowledge of officials and communities regarding conservation-based management principles proved challenging. Existing institutions were targeted for education and capacity building and the program concentrated on enhancing knowledge and skill in prevention of reef degradation as well as sustainable use of the

resource. Increased community participation led within three years to increased catch which in turn enhances community income after management rights were conferred to the coastal community in Mapor, Riau Province (Mujiyani, 2007)

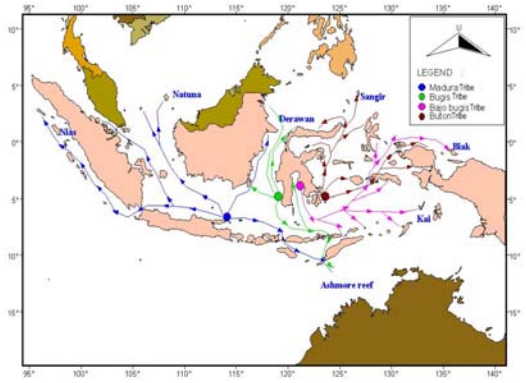

Figure 4. Route of Sea Wondering Fisherman of Madura, Bugis, Buton & Bajo Tribe

All fishermen that joined the COREMAP program understood and voluntarily follow the program, fully realizing the importance of managing coral reef resources. Conflict occurred with non residence fishermen taking resources managed by the local fishermen. Thus acknowledgment of the local community's management right and full transfer of responsibility are important. Control by local community proved efficient from psychological and budgetary viewpoints, since the community was able to control extensive areas at a reasonable cost. Lack of coordination between community officials and law-enforcement officers was observed and negated many fledgling successes.

Control and community awareness programs reduced fishing activities using explosive. While in the past, bombers were considered friendly by the local populace (bombers took only big fish allowing the population to collect the small ones), this attitude is beginning to change The immediate result is that the coral reefs located near human settlement seem to be is in better condition than the more remote ones. This condition is a reversal of that observed a decade ago where the coral reefs near human settlement were the most severely degraded.

Also a community awareness program was directed to all level existing in the communities starting from the decision makers, member of parliament, President, to the local community inhabiting the coastal areas. Overall 63% of the general public and 71% of the coastal communities were aware of the "Save our Coral Reef" campaign (Coremap, 2002). Most effective media were TV and radio programs. In coastal communities and local governments campaign events or a visit by a prominent figure proved efficient.

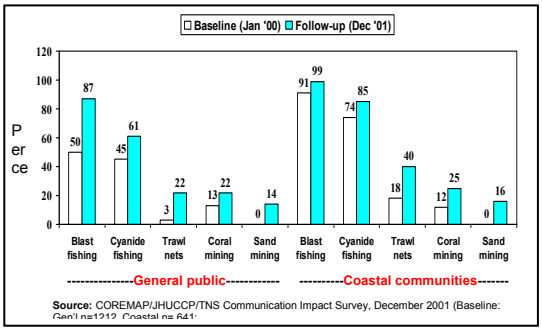

Figure 5. Percent who regard specific fishing techniques as threatening to coral reefs, 2000-2001

Lack of education and scientific knowledge of the coastal communities was a main causes for marine resources degradation.. In Indonesia, formal education curricula are characteristically land-oriented and similar for all schools, whether located on the coastal or far inland. Aware of the importance of formal education, text books on marine life were distributed. For the 6-year elementary school, 7 books; one a teacher-guide, six for grades 1 to 6, were produced. The Central Education Service was involved and the books have been adopted by the Local Education Services.

While coral reef conservation in Indonesia remains challenging, our program has shown that society-wide information, increased education and empowerment of local resource stewards has helped to significantly advance conservation goals.

Abstract. This study characterized and compared the benthic habitats of four banks in the northwestern Gulf of Mexico (Sonnier, McGrail, Geyer, and Bright Banks) and documented potential hurricane damage at these banks. Hurricane Rita, a Category 3 storm, passed 12 km east of McGrail Bank and 24 km west of Sonnier Bank on September 23, 2005. Hydrodynamic hindcast models indicated water velocities of 4 m/s in the vicinity of the banks and estimated maximum wave heights of 13–26 m, which could have exposed even the deeper banks. Results of this study revealed that Sonnier Bank exhibited the lowest live cover at all depth ranges (2–38%) and the highest diversity of all banks, while Bright Bank exhibited the highest live cover (86%). Live cover was significantly different across banks and multivariate statistical analyses using benthic cover data showed significant differences between banks. No obvious signs of hurricane damage were observed at McGrail, Geyer, and Bright Banks; however, a loss of live cover was observed at Sonnier Bank. The results of this study suggest that hurricane impacts to algal and sponge dominated banks may be harder to detect more than a year after a hurricane has passed.

Key words: hurricane, McGrail Bank, Geyer Bank, Sonnier Bank, Bright Bank, Gulf of Mexico

Introduction

Hurricane Rita passed through the Gulf of Mexico in September 2005. Several sensitive habitats within the northwestern Gulf of Mexico were in close proximity to the path of Hurricane Rita, including Sonnier Bank (SB), McGrail Bank (MB), Geyer Bank (GB), and Bright Bank (BB), which were all located within ~75 km of the storm track (Fig. 1). Suspected large wave heights may have exposed some bank caps, even those located at depths of 20–30 m. Preliminary assessments of the coral reef cap (18–29 m) at the neighboring East Flower Garden Bank (EFGB) following Hurricane Rita indicated substantial mechanical impacts: fractured and displaced corals, sediment-scoured corals bordering sand flats, and corals scarred and dented by waterborne objects (Hickerson, EL and Schmahl, GP, pers. comm.). The goals of this study were: 1) to characterize and compare the benthic habitats within four depth ranges at SB, MB, GB, and BB; and 2) to document potential hurricane damage at these banks. Additionally, it was an important goal of this study to distinguish between storm damage and damage from oil and gas activities, which might be apparent at greater depths.

Material and Methods

In order to understand the wave and current conditions in the vicinity of SB, MB, GB, and BB during the passage of Hurricane Rita, a wave study was conducted using hindcast data provided by Oceanweather, Inc. This study consisted of two distinct analyses: (1) a numerical modeling effort using the REF/DIF program to determine the magnitude of wave transformation from the hindcast wave location to the bank locations and (2) an analytical model to estimate the potential currents resulting from the transformed wave conditions.

In April and May 2007, videographic transects were collected by divers and a remotely operated vehicle (ROV) to characterize the benthic habitats of SB, MB, GB, and BB. Previous descriptions of biological communities at banks in the northwestern Gulf of Mexico (Rezak et al. 1985, Boland 1999, Rezak and Bright 1979, Schmahl and Hickerson 2006) were considered during the sampling design for this study.

Four distinct depth zones were sampled within the habitat types described by Rezak et al. (1985; Table 1). The depth discontinuities between the four sampling zones were purposely established to prevent overlap at the margins of each depth zone.

Table 1. Summary of data collected by divers and ROV in four depth zones. D = sampled by diver; R = sampled by ROV; NS = not sampled; "-" = zone not present; number following dash represents number of transects.

Depth Zone (m)	Bank			
	Sonnier	McGrail	Geyer	Bright
22–27	D–2	-	-	-
30–36.5	D–8	-	D–8	D–3
45–50	R–7	R–12	R–4	NS
55–60	R–6	R–8	R–7	NS

Divers videotaped transects within no-decompression diving limits (to ~36.5 m depth). Video footage was collected at a height of 40 cm and perpendicular to the substratum using a digital video camera in an Ikelite® underwater housing fitted with a wide-angle lens and underwater video lights (Aronson et al. 2005). A TrackLink® 1500 High Accuracy Ultra Short Baseline acoustic positioning system (USBL) with two beacons and an accuracy of 0.25 degrees was used to track the location of videotaping divers/ROV. Data were converted into a GIS format to visualize the location of diver/ROV transects in geographic space (Fig. 2).

Eight randomly positioned transects (each 10 m long) were videotaped at SB within the 22 to 27 m depth range. Because these transects were positioned with reference to a single line (pseudoreplicates), the data from these eight transects were pooled, creating a single long transect for statistical analysis. An additional transect was laid in this depth zone, beginning 21 m northeast of the U-bolt and videotaped in a 90° direction. In the 30–36.5 m depth range at SB, GB, and BB, transects were set along depth contours. Continuous and unidirectional video footage began at random locations.

ROV video footage was collected along depth contours in the 45–50 m and 55–60 m depth zones at SB, MB, and GB using a Seabotix LBV 300S-6[2] ROV. The TrackLink USBL system was used to track the ROV and the position of the ROV was recorded in real time. Due to impending foul weather, ROV data was not collected at BB.

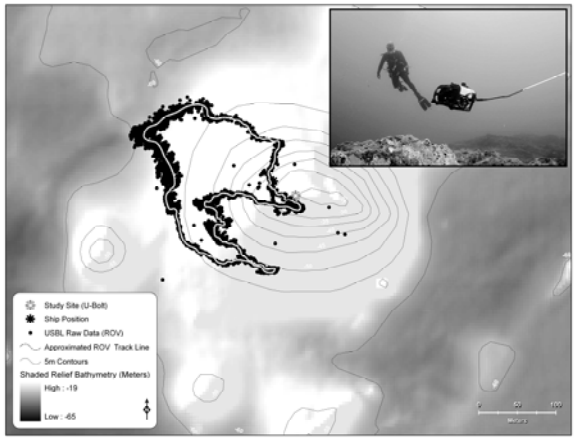

Figure 2: Map of ROV track at Sonnier Bank to and from the ship to a maximum depth of ~60 m. Image courtesy of A. Hazra.

To capture landscape-scale views of all four banks, divers recorded video footage during their descents and along the seafloor. Roving diver video was recorded at 1–2 m above the substrate, while looking down at a 45° angle. The roving diver video was qualitatively analyzed for possible hurricane impacts and compared to video from previous surveys, which acted as an estimate of pre-hurricane conditions and benthic community structure. The ROV also collected landscape-scale views at deeper depth ranges.

Transect video footage collected at SB in the 22–27 m depth range was cut into non-overlapping still images using ULead® VideoStudio® 9. Each 10 m transect yielded ~4 m^2 of benthic imagery. For contour video collected at all other depth ranges, random start times were used to generate 37 consecutive still images from the video footage (4 m^2), which were equivalent to one 10 m transect. A random number of frames were skipped before beginning the next 37 frame transect. Randomly placed dots were then added to each frame using Coral Point Count® (CPCe), for a total of 500 dots per transect. Organisms positioned beneath each random dot were identified to the lowest possible taxonomic level. Quality assurance/control consisted of

independent analyses by trained observers on the same segment of captured video. There was agreement between pairs of observers at least 95% of the time.

Results

Hydrodynamic Model Predictions

The REF/DIF model was run to determine the potential effects of banks on waves generated by the storm. Results showed that wave heights increased dramatically in the vicinity of the banks due to the large difference in water depth between the seabed and the summit of the bank. The modeling effort suggests that wave heights are potentially increased to just below the wave-breaking point in the vicinity of the banks. Therefore, the wave heights from the hindcast study were increased to just below breaking—approximately 60% of the water depth at each bank location—in order to estimate the water velocities induced by the waves on the banks. These transformed waves were then input into the Stream Function Wave Theory program to estimate water velocity. Table 2 displays the maximum bottom velocity and maximum wave height at each bank.

Table 2. Results of the hydrodynamic modeling effort in relation to bank depth and distance from the Hurricane Rita storm track.

Bank	Bank Depth (m)	Distance from Storm (km)	Max Bottom Velocity (m/s)	Max Wave Height (m)
McGrail	45	12	4.0	26
Sonnier	22	24	4.0	13
Geyer	39	58	4.0	26
Bright	33	75	4.5	20

Benthic Characteristics

Live cover data were pooled for each bank and data were square-root transformed in order to perform a one-way analysis of variance (ANOVA). Live cover was significantly different across banks ($F = 16.49$, $df = 3,61$, $P<0.0001$). Tukey's HSD test showed significant differences between all pairs containing SB, as well as between BB and MB (Table 3).

Table 3. Tukey's HSD test performed on square-root transformed live cover estimates from diver and ROV transects. Asterisk (*) denotes significant difference at $\alpha = 0.05$; ns = not significant.

Bank	Sonnier	McGrail	GB	Bright
Sonnier	–	*	*	*
McGrail		–	ns	*
GB			–	ns
Bright				–

Sonnier Bank, the only bank in this study located east of the storm track, exhibited the lowest live cover at all depth ranges (~2–38%) when compared to MB, GB, and BB (~17–86%). SB was dominated by brown macroalgae, sponges, and *Millepora alcicornis* in shallow areas, while deeper zones were dominated by "fine turfs (< 3 mm) and bare space" (TB) and "rubble" (rock or coral rubble - bare or covered in fine turf algae). With increasing depth, percent live cover decreased at SB (22–27 m, 38.3%; 30–36.5 m, 30.1%; 45–50 m, 6.8%; 55–60 m, 1.8%). Qualitative analyses of video footage collected at SB by divers in 1996, 2002, and 2005 showed differences in benthic cover compared to video collected in 2007. Algal and sponge cover appeared to be higher in the previous years. Another notable difference was the apparent disappearance of *Xestospongia muta* colonies. This species was present in 1996, declined to one individual with disease-like characteristics in 2002, and then was not recorded in 2005 or 2007.

McGrail Bank lies only ~12 km west of the storm track and has the deepest reef cap of any bank evaluated in this study (45 m). Live cover at MB ranged from 17–38%. In the 45–50 m depth range, rubble and sand were the dominant features, while live cover (38%) was dominated by macroalgae and hard corals. The coral cover consisted mostly of *Stephanocoenia intersepta* (4.8%) with *Millepora alcicornis*, *Agaricia* sp., and *Montastraea cavernosa* comprising the remaining 0.7%. Because the percent cover of *S. intersepta* appeared to be much higher in some areas within this depth range (ranging from 0–32% within the transect data), multidimensional scaling (MDS) analysis was performed on the 45–50 m transect data based on multivariate cover of the four hard-coral taxa. The MDS plot (Fig. 3) reveals that there is indeed high variability among transects in the composition of the coral assemblage at MB in the 45–50 m depth range.

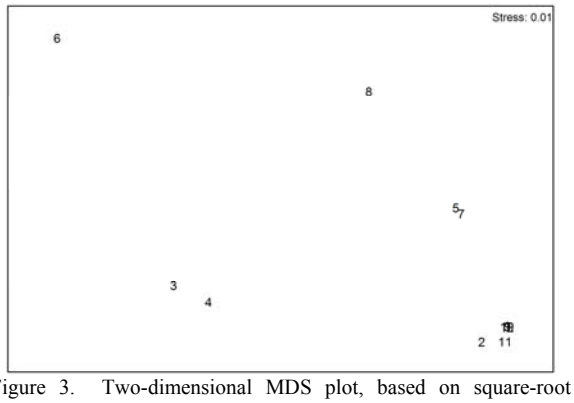

Figure 3. Two-dimensional MDS plot, based on square-root transformed Bray-Curtis similarities, comparing multivariate cover of the four hard-coral taxa at McGrail Bank within the 45–50 m depth range.

In the 55–60 m depth range at MB, rubble and sand were the major benthic components, while live cover (17%) was comprised mostly of algal nodules (6.5%) and the brown macroalga, *Lobophora variegata* (3%).

Previous videos were not available for qualitative analysis. No apparent hurricane damage in the form of overturned or injured corals was observed.

Live cover at GB ranged from 30–60% and was mostly comprised of brown macroalgae, corals, and sponges. Geyer Bank is the only bank evaluated in this study with an observed population of *Tubastraea coccinea*, an exotic, invasive, azooxanthellate scleractinian coral that has recently invaded the Gulf of Mexico (Fenner and Banks 2004). Live cover was 60% within the 30–36.5 m depth range and was dominated by brown macroalgae (42%), with *Sargassum* being the dominant genus at 27%. Rubble and TB were important contributors to overall cover. In the 45–50 m depth range, live cover was ~30%, with brown macroalgae as the dominant taxonomic group at ~22%, and rubble and TB comprising 32% and 31%, respectively, in this depth range. In the 55–60 m depth range, live cover was ~35% and was comprised mostly of brown macroalgae (22%). Rubble and TB accounted for 43% and 12% of the total cover, respectively. Diver video collected at GB in 2003 showed similar benthic cover to the video that was recorded in 2007 with no obvious signs of hurricane damage.

Due to foul weather, only one depth range (30–36.5 m) was surveyed at BB, which exhibited the highest live cover of all four banks examined in this study (86%), with brown macroalgae (44%), green macroalgae (13%), and turf algae (12%) as the dominant groups. Coral cover was ~8% and was comprised of four species: *Millepora alcicornis, Diploria strigosa, Stephanocoenia intersepta,* and *Montastraea cavernosa*. Diver video taken in September 2003 revealed mostly bare substrate, low macroalgal cover, and few large coral colonies. No hurricane damage was observed at BB.

Statistical Analyses

The Shannon-Wiener Diversity Index (*H′*) was calculated for each bank at each depth using the lowest taxonomic group possible. Diversity was highest at SB from 22–27 m, due largely to the variety of sponges present there. Diversity decreased with depth at SB (Table 4). Both GB and MB exhibited the highest diversity values in the 45–50 m depth range. The brown macroalgae accounted for these high diversity values. Notably, diversity at 45–50 m was very low at SB compared to GB and MB. Brown algae distinguishable to genus or species were virtually absent from SB between 45 and 50 m. Turf algae, rubble, and sand were the dominant categories at SB from 55–60 m, accounting for the zero-value of *H′* in that depth range. It should be noted that in this study, turf algal species were lumped into a single taxonomic unit because individual taxa were not distinguishable from video; however, the actual species diversity of turf algae would be expected to be high, and if known, would likely increase the *H′* for the deeper transects at SB.

Table 4. Shannon-Wiener Diversity (*H′*) at all banks and depths surveyed.

Depth (m)	Sonnier	Geyer	McGrail	Bright
22-27	2.86	----	----	----
30-36.5	1.55	1.65	----	1.81
45-50	0.23	2.13	2.08	----
55-60	0*	1.47	0.83	----

*only turf algae, rubble, and sand

Multivariate statistical analyses were performed using benthic cover data at SB, MB, GB, and BB. Analysis of Similarity (ANOSIM) showed significant differences between banks (Global R = 0.54, P = 0.001). Within site comparisons showed less dissimilarity between depths. MDS highlighted the dissimilarities among banks, with depths within sites grouping more closely (Figure 4).

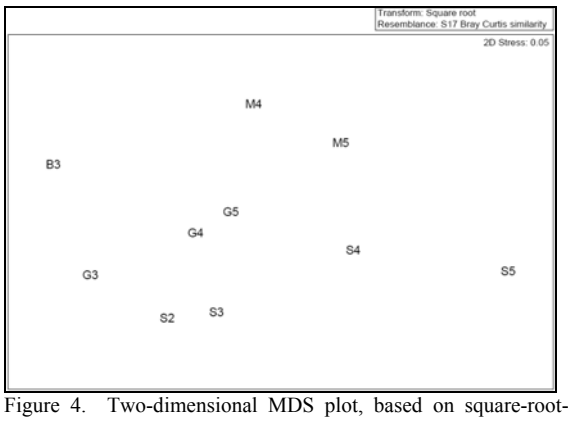

Figure 4. Two-dimensional MDS plot, based on square-root-transformed Bray–Curtis similarities, comparing multivariate benthic cover data among Sonnier, McGrail, Geyer, and Bright Banks at the depth ranges sampled. Data were pooled within depths at each site. Abbreviations: S2, Sonnier Bank 22–27 m; S3, Sonnier Bank 30–36.5 m; S4, Sonnier Bank 45–50 m; S5, Sonnier Bank 55–60 m; M4, McGrail Bank 45–50 m; M5, McGrail Bank 55–60 m; G3, Geyer Bank 30–36.5 m; G4, Geyer Bank 45–50 m; G5, Geyer Bank 55–60 m; B3, Bright Bank 30–36.5 m.

Discussion

Little is known about the effects of hurricanes on benthic communities not dominated by corals (e.g., SB, MB, GB, and BB). This study suggests that hurricane impacts to algal and sponge dominated banks may be harder to detect more than a year after the hurricane has passed. Since the passage of Hurricane Rita, algal communities have had time to re-grow and sponges may have healed/regenerated. Furthermore, corals, sponges, and other organisms that may have been removed from these banks during the hurricane were likely fractured and dispersed by the predicted water velocity of ~4 m/s, leaving little

or no detectable remnants 20 months after the storm. Vast areas of rubble, documented at SB and at deeper depths on MB and GB may have represented hurricane effects; however, this may not be the case as normal reef processes also create rubble zones on banks in the northwestern Gulf of Mexico (Rezak et al. 1985).

A wave study was conducted to better understand the wave and current conditions in the vicinity of SB, MB, GB, and BB during the passage of Hurricane Rita. The REF/DIF model wave height estimates represent the largest theoretical wave heights that may have occurred at each bank cap. Based on these results, larger wave heights may have occurred at banks with caps located in deeper water (i.e., MB and GB). However, it is interesting to note that the analysis of transect video in this study did not show the greatest damages at MB and GB, as might be expected by the results of the wave model. Furthermore, the shallowest bank included in this study (SB at 22 m depth) experienced the most observable damage, with the appearance of bare substrate and rubble fields in the 2007 transect video. While one might assume that the greatest damage would likely occur at banks located closest to the storm track, the results of this study do not support this assumption. MB is located closest to the storm track (12 km); however, no hurricane damages were observed at this bank. Significant damages were detected at SB, which is the only bank in this study located east of the storm track. It is common knowledge that the right side of a hurricane (relative to its direction of travel) is the most powerful portion of the storm in terms of wind speed and storm surge. This may be a contributing reason for the damages observed at SB.

Potential Hurricane Effects

As the shallowest bank located on the east side of the hurricane track, with hindcast water velocities up to 4 m/s and estimated waves up to 13 m, SB likely sustained hurricane damage in late September 2005. Benthic survey results showed that SB had lower live cover than any of the other banks in this study. At the shallowest depth (22 m), divers with previous experience noted that the bank surface appeared very different from previous visits. Areas of bare bedrock appeared in places previously occupied by live cover.

The depth of MB (45 m) may have protected the scleractinians and algal nodules from hurricane damage, even though the hurricane essentially passed over the bank. Wave heights of up to 26 m were modeled to have passed over MB. Undoubtedly, the pressure and velocity of water during the storm affected the top of the bank, even at 45 m depth. However, the absence of baseline data with which to compare the observations and data gathered at MB during this study prevents statistical comparisons and limits our ability to draw inferences from these data. Because ROV footage was taken at night, landscape-scale views were not possible to discern. It may be that hurricane damage was not detected for this reason. The colonies that were observed appeared undamaged; however, the high variability of coral cover observed in the 45–50 m depth range could have been a consequence of the hurricane. On the other hand, that high variability could reflect the patchiness of the benthic biota caused by variability of coral recruitment or post-settlement processes, or previous perturbations.

Video footage from 2003 was analyzed qualitatively for pre-hurricane conditions at GB and BB. The subject of both videos was the fish populations at these banks; therefore, a thorough characterization of the benthic community structure was not possible. Video from BB showed largely bare, uncolonized areas, with *Lobophora variegata* being the only discernible macroalgal genus. Video from GB showed coverage of the benthos by brown macroalgae, including *Sargassum* spp., which was the dominant macroalgae in 2007. From these pre-hurricane videos we can conclude: (1) that the unique biological characteristics were not established after the hurricane; and (2) that as of April–May of 2007, the benthic assemblages had recovered to some extent.

Patterns of spatial variability in distribution of benthic invertebrates and algae at Sharm el Sheikh (South Sinai, Egypt)

Abstract. A survey of benthic community was conducted as part of a project to construct an Underwater Observatory on the coast of Sharm el Sheikh (Egypt). To provide the first step of the EIA based on a "Beyond BACI" design, the spatial distribution of benthic invertebrates and algae was studied at a hierarchy of spatial scales: 5 sites, 3 areas within each site and 20 1m^2 frames within each area were randomly selected. Plots were sampled using the photo-quadrats method. A combination of univariate and multivariate analysis of the percentage cover was used to describe differences in the abundance of organisms identified at the genus level and, when necessary, grouped into broader categories. Results showed significant differences in the distribution and abundances of organisms among sites as well as among areas, indicating that abundances varied at the scales of hundreds and tens of meters along the coast investigated. These results are likely to be due to spatial differences of the hydrodynamic conditions of the studied sites, other than to stochastic events. One of the sites with the lowest percentage cover of living organisms was suggested as the most suitable to place the Underwater Observatory in order to minimize the impact of the structure.

Key words: Spatial variability, Coral reef, Red Sea, Photo-quadrats, EIA

Introduction

This study is a part of the "Pilot project for the sustainable development of environmental sound management in South Sinai, Sharm el Sheikh, Ras Mohammed National Park" funded by the Italian Ministry of the Environment. Within this project, the construction of an Underwater Observatory close to the Visitor Center of the park was proposed. In response, the coast of Sharm el Sheikh was surveyed to provide information about spatial variability in distribution of benthic invertebrates and macroalgae.

Variability in the distribution of natural species can occur at different spatial scales (Kennelly and Underwood 1992; Underwood and Petrait 1993; Underwood and Chapman 1996; Connell et al. 1997, Benedetti-Cecchi et al., 1998; Menconi et al. 1999; Ferdeghini et al. 2000; Balata et al. 2006). Documenting the spatial scales at which variability in the abundance of organisms occurs can help to focus attention on the relative importance of different ecological processes that can determine the patterns observed (Underwood and Chapman 1996).

In this study, the sampling procedure was designed in order to be the first step of an Environmental Impact Assessment based on a "Beyond BACI" (Before-After, Control-Impact; Underwood 1991) design.

The logic of this design is to separate the spatio-temporal natural fluctuations of the structure of benthic assemblages from those due to anthropogenic activities. Thus, an appropriate analysis would consist of properly replicated sampling several times before the development and several times after in potentially impacted and in reference locations. From these data, it is possible to ascertain interactions in impacted and control sites through time (Underwood 1991, 1992, 1993, 1994).

Moreover, documenting the spatial distribution of living organisms was essential to suggest the most suitable stretch of coast to place the Underwater Observatory.

Materials and Methods

The study was carried out at Ras Mohammed National Park along the coast of Marsa Ghoslani bay (Fig. 1). Blocks of organic framework of dead and living corals characterized the substrate of the study area.

A nested sampling design was used at a hierarchy of spatial scales: 5 sites (100s of m apart), 3 areas within each site (10s of m apart) and 20 replicates of 1m^2 frames within each area were randomly selected in the Northern part of Marsa Ghoslani bay (Fig. 2).

Plots were sampled using the photo-quadrats method (English et al. 1997; Acunto et al. 2001; Hill

and Wilkinson. 2004). All samples were collected at a depth of 10 m on a gently sloping rocky bottom (with an angle ranging from 10 degrees to a maximum of about 15 degrees).

Figure 1: Study location along the coast of Sharm el Sheikh, Egypt.

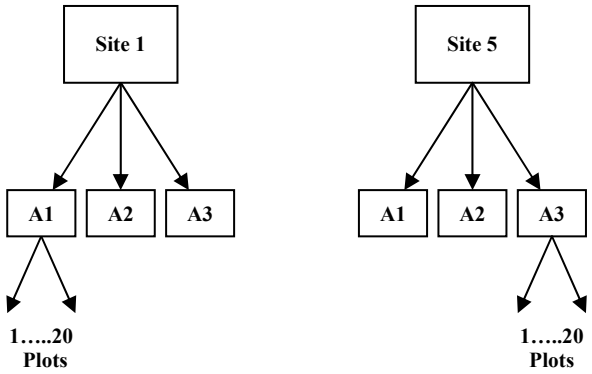

Figure 2: Sampling design.

A permutational multivariate analysis of variance was used to study the spatial variability among sites and areas by PERMANOVA (Anderson 2001; McArdle and Anderson 2001). This computer program uses permutation procedures to obtain the null hypothesis distribution (indicated as "pseudo" *F*) and *P*-values for the tests (including interactions), for any balanced multi-factorial ANOVA design. It is a non-parametric test.

The analysis consisted in a 2-way model with SITE (5 levels) as a random factor, AREA (3 levels) as a random factor nested in SITE. This analysis was performed using cover of sessile invertebrates identified at the genus level (De Vantier et al. 2006; Balata et al. 2005; Wielgus et al. 2004) while algae grouped into morpho-functional groups (Littler 1980; Littler and Littler 1980; Steneck and Dethier 1994; Ateweberhan et al. 2006). A two-dimensional nMDS (non-metric multidimensional scaling), based on the centroids of replicate areas, was used for a graphical representation of the assemblages. Distances among centroids were obtained using principal coordinate axes from the original Bray–Curtis similarity index matrix.

The same model was used to perform the analysis of variance (ANOVAs) on total number of taxa, total percentage cover of organisms, percentage cover of the morphological forms of hermatypic corals (Veron 2000), soft corals, sponges and filamentous algae.

Results

The nMDS showed Site 3 separated from all the other sites. The dispersion of the centroids representing areas within each site were homogeneous with the exception of Site 4 where one area scattered far from the others (Fig. 3).

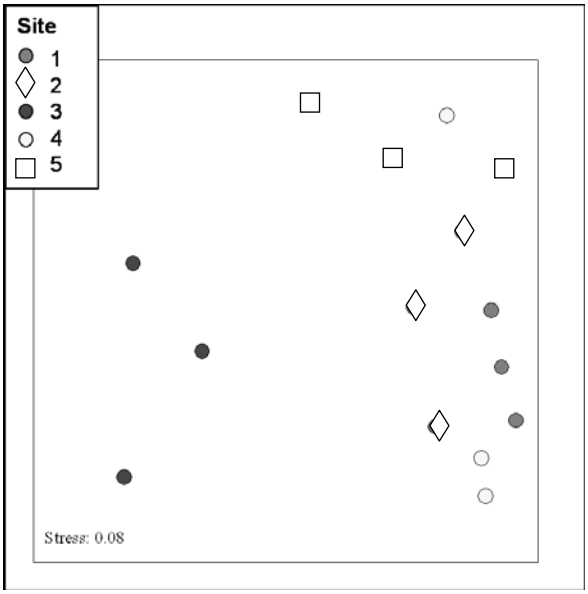

Figure 3: nMDS calculated on the cover values of benthic organisms for each Area

PERMANOVA showed significant differences in the structure of assemblages at both spatial scales investigated (Table 1).

ANOVA showed an analogous pattern, but branching corals showed significant differences only among sites while filamentous algae, sponges and the total number of taxa showed significant differences among areas (Table 2).

The mean percentage cover of all organisms was higher at Site 3 (30.15 ± 2.4 considering the mean among areas) than in the other sites with values between 11% and 16%. Filamentous algae were the most abundant organisms at all the sites with the exception of Site 3 where the percentage cover of massive corals was highest (Fig. 4).

Discussion

Our findings indicate that the structure of the assemblages and the abundances of dominant taxa varied at the scales of tens and hundreds meters along the investigated coast.

Understanding the scales of natural variability of the response variables analysed is a fundamental requisite for the design and optimisation of any environmental sampling programme (Underwood 1991). As a first step of the environmental impact assessment based on a "Beyond BACI" design, the variability observed during this study will be taken into account and compared with the results of future sampling.

One of the studied sites (Site 1) showed a low cover of living organisms; therefore this site can be considered, from an ecological point of view, the most suitable for the construction of the Underwater Observatory. Patterns of distribution showed that Site 3 hosted the largest abundances of corals. This was likely due to spatial differences in the hydrodynamic conditions of the studied coast. Even if further investigations should be necessary to confirm this hypothesis, it is possible that recruitment and development of corals at Site 3 is enhanced by exposure to waves and currents greater than at the other sites.

History of previous disturbances that have occurred along this coast (storms, bleaching events and *Acanthaster planci* outbreaks) could explain low percentage cover of scleractinian corals and the relative high abundance of filamentous algae. However, the observation of numerous small colonies suggests beginning recovery of corals (authors personal observations).

Acknowledgement

We would like to thank Dr. David Balata for his contribution to this work and the scientists of EEAA (Egyptian Environmental Affair Agency), in particular Dr. Essam Saadalla, for their collaboration during sampling activities and assistance in the field. A special thanks to our friend Anna Proietti-Zolla for her collaboration to this work and for her invaluable human support.

Abstract The Brazilian Ministry of the Environment launched the Coral Reef Conservation Campaign in 2001, understanding that public awareness is crucial to environmental conservation. The main objective of this campaign was to promote principles of environmentally friendly behavior based on the international "Leave No Trace" Campaign. In the first phase of the Campaign, managers of nine protected areas established in coral reef sites were invited to be partners. In 2005, with the financial support of the National Fish and Wildlife Foundation, environmental training courses were developed targeting the five most visited Brazilian beaches with coral reefs (Maracajau, João Pessoa, Porto de Galinhas, Tamandaré and Porto Seguro). Various outreach materials were prepared: posters, folders, textbooks, stickers, t-shirts, caps and DVD-videos. We also established partnerships with airlines and a public TV channel to broadcast the video, and supported its use at events, such as "Clean Up Day", in three beaches: Natal, Tamandaré and Maceió. In this paper, we describe the methodology, dissemination and partnership strategy used, and we discuss the results and evaluation of the awareness campaign.

Keywords: Coral reef conservation, Brazil

Introduction

Coral reefs are distributed over 3,000 km along the northeastern coast of Brazil, representing the only coral reef ecosystem in the South Atlantic (Maida and Ferreira 1997). Most of the reef building corals are endemic, forming structures not found in any other part of the world. About 18 million people live on the coastal zone of the Brazilian northeastern region. The health, well-being and subsistence of these coastal populations benefits directly from the environmental quality of the coastal ecosystems, especially of the coral reefs (Maida et al. 1997). Nevertheless, due to unsustainable use of resources over the years, several Brazilian reefs, mainly coastal ones, are showing increasing signs of stress. It is imperative that actions be taken to protect these ecosystems. Public awareness of coral function and value seems to be fundamental to achieving conservation.

The Brazilian Ministry of the Environment (MMA) launched the "Coral Reef Conservation Campaign.", which promotes environmentally aware behavior based on the international "Leave No Trace" Campaign. Ecotourism in Marine Protected Areas is considered the best option for making these areas financially self-sustainable. If, however, visitation is uncontrolled and careless, it can become a serious threat to the protection and conservation of local biodiversity. In this case, public awareness of the roles and importance of wild areas is a key step for environmental conservation. Building on this principle, the MMA decided to launch an awareness campaign directed to the visitors of these protected areas. The first phase of the Coral Reef Conservation Campaign was prepared by the Brazilian Ministry of the Environment and the Coastal Reefs Project in 2001/2002 (MMA, 2002). Its objective was to conserve coral reefs by reducing harvesting on reefs and controlling damage or destruction of the coralline structure. In 2004, the Brazilian Ministry of the Environment received a grant from the National Fish and

Wildlife Foundation to continue the Campaign in partnership with the Mater Natura Environmental Studies Institute to expand the campaign, showing the importance of coral reef protection to tourists and environmental agents, managers of protected areas, teachers and environmental volunteers. Activities included: (i) producing printed material; (ii) producing a video with coral reef information for distribution to tourist centers, airplanes, local community centers, and dive shops; (iii) launching a training program for managers of protected areas, teachers, tourist guides and volunteers; and (iv) evaluating the campaign.

Material and Methods

This project aimed to extend the original campaign "Leave No Trace" to coastal and marine zones, specifically for coral reefs, with the production of educational brochures and a DVD. As the primary goal of campaigns for the conservation of wild areas is the creation of behavioral guidelines for tourism and leisure activities in terrestrial areas, the campaign was followed by developing suitable guidelines to be applied to marine ecosystems in Brazil. Coral reefs were the first to be selected. A public awareness campaigns on the role and importance of the population was considered the principal measure to ensure protection of these ecosystems. The overall purpose was to create the most attractive products and a logo that identified the campaign (Fig 1).

Figure 1: Logo of the campaign

Three different types of campaign materials were designed (folder, poster and booklet, www.mma.gov.br.

In the second phase, activities were reinforced in five reef areas that were suffering extensive impacts due to coral collection, fishing, sedimentation, pollution and actions resulting from urban occupation and unplanned tourism. In 2004, the Coastal and Marine Division was created within the Brazilian Ministry of the Environment to become the focal point of the campaign. The training program was launched in the states of Rio Grande do Norte, Paraíba, Pernambuco and Bahia.

Activities were: DVD and new dissemination materials, a training program and the evaluation of the campaign, analyzing the courses and the outreach material through questionnaires and interviews with the participants of the courses. The training program was held in the beaches of Maracajau, João Pessoa, Porto de Galinhas, Tamandaré and Porto Seguro and consisted of at least 10 hours of lessons, including topics on coral reefs, the importance of conservation, Brazilian coastal protected areas, coral reef monitoring and techniques to minimize impacts on natural environments. The project evaluation report included four criteria and indicators: (1) participation rate: an indicator of the number of people interested in courses; (2) number of committed implementers and a description of participant's involvement in the campaign; (3) the level (presence/absence) of municipal endorsement of the program and the integration of the campaign in other community programs (total number of activities launched with the campaign); and (4) the attitude toward coral reef conservation among tourists. The tourists' evaluation was prepared by five environmental agents from the local community.

Results

The campaign began with the distribution of printed material to protected areas and, in the second phase, the final product of the project was to engage institutions and stakeholders in five areas highly endangered by intense tourism. The courses were attended by 180 persons and the outreach material distributed to schools, tourist centers, local communities, universities and municipalities (Fig 3).

Figure 3: Printed material of the campaign

A set of guidelines based on the major principles people should bear in mind when visiting reef areas, regardless of whether these areas are protected or not, was produced. These guidelines are: a) scuba diving can be the best way of exploring coral reefs, but divers should contact professional divers and managers of protected areas for information, and follow the protected area's rules when planning to visit the area; b) take care to drop anchor onto the sand, because when set onto the reefs, corals and other organisms are damaged, in addition to it being illegal; c) refrain from stepping or touching the coral, they are very fragile organisms; d) feeding fish is harmful to their health; e) when diving, use waterproof skin lotion; f) shells, corals and starfish provide shelter to other organisms, so should not be removed from their habitat; g) divers must maintain control of diving equipment so that it doesn't bump against the reef; h) avoid wearing fins in shallow waters because they can damage corals and other organisms and suspend sediments; i) move slowly when diving in order not to scare animals away; j) the law prohibits buying and selling handicrafts made from corals, so do not purchase these; k) try to obtain information on the tide times and cycles in order to avoid unexpected, potentially dangerous situations; l) do not use explosives, liquid bleach and other chemicals for fishing as these are extremely harmful to the reef environment and their use is prohibited by law; m) avoid using harpoons and fishgigs, as they scare animals away; n) when visiting a natural area, take the trash you produce back with you; and o) do not collect anything, make sure that the only things you take away from the reefs are memories and pictures (Fig. 4).

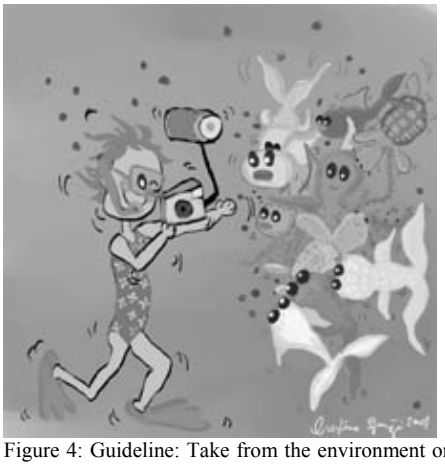

Figure 4: Guideline: Take from the environment only memories and pictures

The course evaluations ascertained that the activities and the outreach material were appropriate for communicating about coral reef ecology and the campaign for minimum impact conduct. It also provided an opportunity to discuss coral reef issues among the various local institutions, who suggested more courses and the creation of a coral reef network. The results of the campaign evaluation show that at some beaches, local agents gave lectures to the public, explained the issue in schools, carried out a Clean Up Day, and distributed posters in shops and restaurants and stickers and folders in boats. The evaluation of the attitude toward coral reef conservation among tourists resulted from 168 interviews in September 2007, to acquire information on visitor awareness and behavior towards coral reef areas in the five beaches of the project. Out of the 168 tourists interviewed, 144 said that they do not buy handicrafts made with coral and 99 do not feed fish when visiting a coral reef area. They chose a coral reef beach because of its beauty, some have marine parks and they could dive and see the coral reef ecosystem. This information shows that in some places there is concern for environmental protection. A case in point is the marine protected area of Recifes de Coral, in Maracajau beach. Its council created rules like limiting the number of boats that can use the area, established the presence of environmental guards and volunteers that explain the importance of coral reefs. In João Pessoa, a large campaign was carried out in the summer for tourists. In

Porto de Galinhas, the number of boats is limited and in Tamandaré, the Pernambuco Environmental Company carried out an environmental education program and set up an environmental library. In addition, we established a partnership with a Brazilian airline to show the coral reef DVD in the airplanes that fly to the northeast of Brazil and to support the Clean Up Day activities in three beaches: Natal, Tamandaré and Maceió. These specific events were organized by local NGOs: Oceânica, in Rio Grande do Norte, the Pernambuco Environmental Company in Tamandaré and the Mergulha Maceió dive shop in Maceió. These events attracted more than 200 volunteers. In Porto Seguro, we received support from the Coral Vivo Project, which developed a coral reef research project and used some campaign material to inform the tourists.

Discussion

In Brazil, some environmental education and awareness raising initiatives have been specifically developed for the coastal zone. Some of these are aimed at diving activities or at attempting to establish underwater interpretative trails. The distribution of information material in itself is not the only way to meet the broader objective of responsible conduct, but it has an important role in the comprehension of certain concepts. The basic principle behind an awareness raising campaign is to inform a group about the importance of the conservation and the minimum impact conduct. The training courses and the outreach material are a way to reinforce the conservation activities developed by some institutions in the coast. One possible means of evaluation is to hand out questionnaires to the visitors of the areas, before and after they receive the material, on their attitudes with regard to the environment or their knowledge of the fragility, value and function of the particular ecosystem. The Ministry of the Environment carried out a survey with the participants, tourists and environmental agents on the receptiveness of the Campaign and is also using the campaign in 2008 to disseminate the International Year of the Reef.

Voluntary Standards as a Tool for Increasing the Sustainability of the Marine Recreation Industry and Improving MPA Effectiveness in Hawaii and Mesoamerica

R. MacPherson[1], R. Wilson[2], L. Foote[3]

1) Conservation Programs Director, Coral Reef Alliance, 351 California Street, Suite 650, San Francisco, CA 94104
2) Program Manager, Coral Reef Alliance, 351 California Street, Suite 650, San Francisco, CA 94104
3) Hawaii Field Manager, Coral Reef Alliance, 351 California Street, Suite 650, San Francisco, CA 94104

Abstract. Standards have a long history of improving service quality and safety in a wide range of industries. Successful businesses benefit from standards both by actively participating in the standardization process and by using standards as strategic market instruments. The Coral Reef Alliance (CORAL) recently completed a process in which marine recreation industry stakeholders in Hawaii and along the Mesoamerican Barrier Reef (MAR) worked in unprecedented collaborations to develop voluntary standards that will measurably improve and sustain environmental performance in scuba diving, snorkeling, boat operations, and marine life viewing. Engaging a standards committee comprised of representatives from marine recreation, conservation NGOs, tourism industry associations, marine recreation suppliers, marine park managers and government agencies, scientists, divers, local community groups, and traditional communities, CORAL is now testing the implementation of these standards and providing technical and financial support for locally based conservation initiatives. It is expected that this process will enhance adoption of standards throughout the marine recreation industry, increase industry support for marine protected areas (MPAs), and lead to the development of extensive conservation alliances, which enhance MPA effectiveness and improve the economic and environmental sustainability of marine recreation in Hawaii and Mesoamerica.

Key words: Standards, Sustainability, Tourism, Hawaii, Mesoamerica

Introduction

In areas of high-volume tourism, repeated direct contact with the reef poses an immediate threat. Hundreds of boat groundings and hundreds of thousands of tourist interactions each year reduce sections of coral reef to rubble. Human contact also reduces coral's ability to cope with stressors such as rising sea temperatures and diseases.

The development of voluntary standards for marine recreation operations provides detailed requirements for environmentally friendly and safety-conscious marine tourism businesses in the areas of diving, snorkeling, boating, and marine life viewing. The voluntary standards are crafted to be flexible and can be used by a variety of groups, including:

- Concerned tourists: to help them choose sustainable and safe marine excursions
- Marine tourism businesses: to evaluate and improve their own practices
- Non-governmental organizations and governments: as a basis for creating their own standards
- Bulk purchasers like cruise ships: to select sustainable and safe business partners

This paper offers two contrasting case studies of how voluntary standards development can be embraced, as experienced in Mesoamerica, or initially rejected, as seen in Maui, Hawaii, by stakeholders. Key lessons learned in standards development are identified to assist with future initiatives.In addition, unique challenges to widespread standards implementation are indentified. For example, the exponential growth of cruise ship tourism in recent years-carrying an estimated 6 million tourists to Mesoamerica in 2004 alone – presents a new impact that must be addressed in this region's overall marine conservation efforts. Ensuring cruise lines both support and contract with local tourism operators who implement the voluntary standards will be a critical test of long-term viability and efficacy of standards as a tool for resource managers.

Case Study -Mesoamerican Reef (MAR)

Material and Methods

CORALfacilitated a highly participatory process to develop the world's first Voluntary Standards for Marine Recreation in the MAR System—Scuba Diving Services, Snorkeling Services, and Recreational Boat Operations.Starting in early 2005, over 180 participants from across the four countries of Mesoamerica (Mexico, Belize, Guatemala and Honduras)representing marine tour operator associations, park managers and conservation NGOs, the cruise ship industry, scientists, concerned divers and individuals from the local communities worked together to develop and implement these voluntary standards andinitiate local and regional conservation projects throughout Mesoamerica.

The widely recognized due process practices defined in the Standards Engineering Society's standard SES-2, Model Standards Development Procedure, were followed in developing these voluntary standards. All drafts, comments, discussions and balloting were accomplished online simultaneously in Spanish and English.

Existing guidelines, preferred practices, and codes of conduct that have been developed by a number of organizations were considered for adoption, but were found to be insufficiently prescriptive and specific. Their focus was directed more towards tourist behavior rather than the conduct and responsibilities of the marine recreation operators and their staff.

Additionally, with respect to the development of the *Voluntary Standards for Recreational Scuba Diving Services*, the European Committee for Standardization's EN 14467:2004, Requirements for Recreational Diving Service Providers, was thoroughly reviewed. However, it was determined that too many additions and exceptions would have to be incorporated to address sustainable tourism issues, particularly regarding the environment, that are critical to application on the Mesoamerican Reef.

In July 2006, the Voluntary Standards were unanimously approved, and then published in May 2007. To date, there is widespread support for standards implementation in the region. With continued education and training on sustainable tourism and reef conservation issues, region-wide implementation is gradually becoming a reality.

Long-Term Assessment

Voluntary standards implementation and assessment consists of a three-part program: 1) a self-evaluation consisting of checklist and narrative progress reports of operator's own performance against the standards, 2) peer-to-peer evaluation across tourism operators using identical checklists and narrative evaluation, and 3) an anonymous third-party "secret shoppers" program to gain additional verification data on operator performance. Data gathered from this testing phase identifies challenges for widespread adoption of the standards, and informs the future direction of work in promoting sustainable marine recreation in each region.

Results

By early 2008, several businesses in Mexico and Belize have been assessed and are demonstrating implementation of standards and good practices. As proof of concept, three companies in Cozumel, Mexico, which collectively carry more than 75,000 tourists into the Cozumel National Marine Park each year, are rewriting company policy manuals to incorporate requirements from the marine recreation standards related to staff training, visitor management and briefings, and operation of vessels. **CORAL** acknowledges this as a significant indicator of early willingness to reassess the business-as-usual mentality in favor of reef (and ultimately, business) sustaining practices.

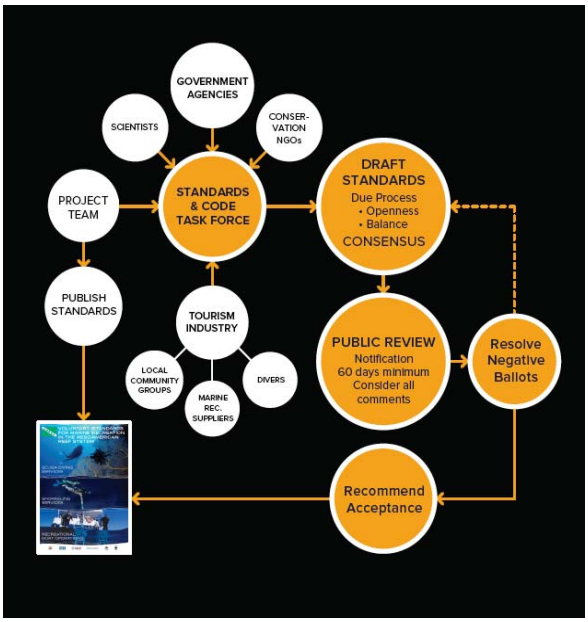

Figure 1: Successful process in Mesoamerica.

Case Study – Maui, Hawaii

Material and Methods

In 2006 CORAL was invited by the State of Hawaii Department of Land and Natural Resources, Division of Aquatic Resources to facilitate a voluntary standards development process on the Island of Maui. In contrast to marine tourism along the MAR, Maui's marine recreation landscape is highly politicized, heavily regulated, and relationships between resource managers and marine recreation operators are fractured. With the successful process experience in Mesoamerica, CORAL applied a similar approach to voluntary standards development on Maui.

Standards development on Maui temporarily stalled in early 2008 as a result of:

1. The State of Hawaii rewrote the Recreational Impacts to Reefs Local Action strategy to include language suggesting intent to regulate operator activity within marine protected areas based on the voluntary standards. This had a chilling effect on operator stakeholders who suddenly doubted whether the standards were truly voluntary.
2. The County of Maui threatened to close public beaches to all commercial recreational activity, raising concerns that a crackdown on recreational operators was imminent.
3. Following the sinking of a dive boat inMolokini Shoal Marine Life Conservation District, a $500,000 fine was levied against the owner of the boat.

Results

The multi-stakeholder voluntary standards development process on Maui broke down by late Summer 2008. The recreational diving community disengaged from a process where interests outside of the dive operators weighed-in on their business operation. As a result, a small faction of resistant dive tourism operators took it upon themselves to craft their own set of recreational diving guidelines. Not technically standards, these guidelines lack broad stakeholder inclusion and discussion. Though the Maui process stalled, a new multi-stakeholder standards development process was launched along the Kailua-Kona coast of the Big Island of Hawaii and shows early signs of buy-in and collaboration.

Discussion

If developed through an industry-led, consensus-driven process and adopted as day-to-day practice by marine tourism operators, voluntary marine recreation standards are attainable, affordable, and offer a means to dramatically reduce tourism's ecological footprint on coral reef protected areas. Some very clear lessons learned were identified from the MAR and Hawaii initiatives:

- Cultivate industry ownership of the voluntary standards
- Promote transparency throughout the process
- Facilitate locally-based partnerships and coordination to implement standards and support conservation initiatives
- Be prepared for challenges and delays based on fear of regulation
- Utilize incentives and momentum to promote implementation

Abstract. Although capacity building can potentially empower local communities with the ability to tackle socio-economic impacts of environmental change, evaluations of Integrated Coastal Zone Management (ICZM) performance can reveal limited interests in advancing community developments. This weakness has been apparent in Southern Belize ICZM, where there has been lack of communication between government ministries, local Non-Governmental Organisations (NGOs), and local communities. To address this, we undertook a capacity building exercise which involved all these sectors in Southern Belize, and developed a series of learning outcomes, linked to scientific goals. Surface areas of 523 individual coral specimens were measured, and recruitment dates were then modelled. We showed that hurricanes and severe storms limited the recruitment and survival of massive non-branching corals of the Mesoamerican barrier reef and on patch reefs near the Belize coast in the Caribbean, and suggest that marine park managers may need to assist coral recruitment in years where there are hurricanes or severe storms. From this scientific base, our project successfully engaged government and community-based partnerships in delivering realistic goals for the future of ICZM in the region.

Key words: tropical storms, cyclones, climate change, global warming, coral growth, fisheries, conch, lobster, snapper, community education, empowerment.

Introduction

Capacity building by engagement has been used in many communities where there are inherent and long-standing challenges to sustainability (Crabbe 2006), for example in Marine Protected Areas (MPAs) (Chircop 1998). While many, if not all, capacity-building programmes involve building competencies and empowerment in local communities, fewer involve policy makers or government officials (Mequanent and Taylor 2007). Capacity building is widely recognised as a central feature of Integrated Coastal Zone Management (ICZM) (Balgos 2005). However, although increased community capacity can potentially empower local communities with the ability to tackle socio-economic impacts of environmental change, evaluations of ICZM performance can reveal limited interests in advancing community developments. This weakness has been apparent in Southern Belize ICZM, where there has been lack of communication between government ministries, local Non-Governmental Organisations (NGOs), and local communities.

Since the Rio declaration on Environment and Development in 1992, the emphasis on capacity building and the transfer of technological knowledge and scientific understanding has encompassed four areas: legal and administrative capacity, financial capacity, technical capacity, and human resources capacity (Cicin-Sain and Knecht 1998). We wished to address the last two of these areas in Southern Belize by strengthening local research facilities and developing local communities' capacity to conserve and manage marine living resources (Wescott 2002). While developing capacity for coastal management has been achieved in the absence of government (Jorge 1997), we wished to involve the Belize government fisheries department in our study in order to facilitate future policy development.

This paper describes the development of a series of learning outcomes, which, for the first time, engaged government and community-based partnerships in

delivering realistic goals for the future of ICZM in the region. This paper examines three key areas specific to the Southern Belize MPAs:

1. Needs to address for the marine reserves
2. Tactics for leading, educating and supporting issues regarding sustainable development in Southern Belize
3. Development of policy issues for a better marine resource management zoning plan.

Material and Methods

There are two major coral reef areas in Southern Belize, the Sapodilla Cayes Marine Reserve (SCMR, a World Heritage Site), and the Port Honduras Marine Reserve (PHMR) (Fig. 1). The SCMR is a 125 km^2 reserve that has been under collaborative management between the Belize Fisheries Department and the Toledo Association for Sustainable Tourism and Empowerment (TASTE) since its declaration in 1996. The PHMR is a 414 km^2 reserve, and has been managed by the Toledo Institute for Development and Environment (TIDE) since its declaration in January 2000.

Figure 1: Coral reef Marine Reserves in Southern Belize. The Sapodilla Cayes Marine Reserve (SCMR), in dark grey shading to the left of the figure, comprises the southern end of the MesoAmerican Barrier Reef, and includes Seal Cay, Frank's Cay, Nicholas Cay, Hunting Cay and Lime Cay. The Port Honduras Marine Reserve (PHMR), in dark grey shading to the right of the figure, is close along the coast near Punta Gorda Town, and includes Frenchman's Cay and the Snake Cayes. Adapted from Crabbe et al. 2008a.

The key aims and objectives of the capacity building exercise were:

1. To increase the Belizean participants' capacity to lead, educate and support issues regarding sustainable development in Southern Belize; and
2. To promote networking throughout organizations managing marine resources, enhancing their power to collectively influence policy decisions in Southern Belize.

The capacity building team consisted of one officer from the Belize Fisheries Department, three senior officers from NGOs involved in managing Belize MPAs (TIDE, TASTE and Friends of Nature), and a Facilitator from the UK. These individuals were chosen because they had direct contact with both NGOs (Non-governmental organisations) and CBOs (Community-based organisations), and the government Fisheries Department, thus maximising exposure of capacity-building while keeping the numbers of participants within workable limits. Scientific measurements on coral reef colonies were conducted by the participants as described (Crabbe et al. 2008a). Daily meetings, lasting between 1-2 h,

took place on Lime Caye in the SCMR, Abalone Caye in the PHMR, and in Punta Gorda Town, over a 10-day period in August 2007 (Crabbe et al. 2008b). Discussions, led by the Facilitator, employed a modified nominal group technique (Sample 1984) to identify priorities related to personal action plans. Four rounds were employed; round one was based on the Delphi technique and further rounds on the nominal group technique approach (McCance et al. 2007). Specifically, after initial meetings which revolved around frank discussions on the interface been the Fisheries Department and MPA management by NGOs, each participant developed a personal action plan to facilitate and improve the sustainability of the MPAs in Southern Belize. There was repeated iteration of these plans between the participants, and the final production of a policy proposal for sustainable management of the marine reserves, Sapodilla Cayes and in Port Honduras.

Results

Our scientific work, described in Crabbe et al. 2008a, showed that for both the PHMR and the SCMR, there were significantly more non-branching massive corals recruited in non-hurricane years (mean 7.7 ± 5.6) than in hurricane years (mean 3.8 ± 2.9; p=0.011). When years with tropical storms are added to the years with hurricanes, there was significantly lowered coral recruitment (mean 4.7 ± 4.3) relative to non-storm or hurricane years (mean 7.4 ± 5.7; p=0.019).

The group then went on to develop personal action plans (Crabbe et al. 2009) and a set of learning outcomes by which the partnerships between government, NGOs and communities can improve ICZM. The learning outcomes are itemised below:

1. Management plans need to be passed into law. The involvement of the government fisheries officer as a partner is key to this outcome.
2. Zonation needs to be re-designated to balance stakeholders' wishes and evidence-based fisheries catches.
3. Participants will develop a community-based research programme.
4. Data need to be more accurate in the future.
5. Co-management plans between NGOs, communities and the Fisheries Department need to address the problem of illegal fishermen from outside Belize (Guatemala, Honduras) as well as from Belize.
6. Regular public meetings of stakeholders need to be fostered, as do regular education events.
7. Effectiveness of zoning needs to be quantified.
8. Alternative livelihoods for fishermen (e.g. in the tourist industry) needs to be fostered and maintained.
9. Tourists need to be monitored.
10. Effective management needs to be linked to the Belize economy. Fishing (conch, lobster, snapper, particularly in Southern Belize,) is an important part of the country's Gross Domestic Product (GDP).
11. NGOs need to link together.
12. Regular information sharing with all stakeholders, from the politicians to the local communities, needs to be maintained.

Discussion

Multiple stressors, hurricanes and bleaching, have caused significant disturbances to populations of coral recruits in Belize (Mumby 1999; Crabbe 2009). While we have not measured coral recruitment directly in this study, our modelling work has shown that hurricanes and severe storms have limited the recruitment and survival of massive non-branching corals on the fringing reefs near Discovery Bay (Crabbe et al. 2002; 2004), and here we show that the same is true for non-branching corals of the Mesoamerican barrier reef in the Sapodilla Cayes, and for corals on patch reefs in the Port Honduras Marine Reserve near the Belize coast in the Gulf of Honduras. What our work suggests is that marine park managers may need to assist coral recruitment and settlement in years where there are hurricanes or severe storms, by setting up coral nurseries (Forsman et al. 2006) and/or natural or artificial high rugosity substrate on the reef (Crabbe et al. 2008a).

Marine Reserves are an important tool in sustainable management of the Belizean coral reefs (Cho 2005; Williams and Polunin 2000). However, it is important that they share regulation, enforcement and conservation, underpinned by scientific research. We have already successfully transferred scientific expertise to Belizean participants for their use in generating scientific evidence to underpin future management and conservation decisions (Crabbe et al. 2009). Here, we have identified a number of key issues in marine reserve management in Belize than need to be addressed. Those issues, and the tactics employed by the participants in this project, will help ensure renewal of policy developments appropriate to the marine reserves in Belize.

The need for case studies in building integrated coastal management capacity has been powerfully made (Hills et al. 2006). Our study reinforced the idea that co-operative research improves capacity building and encourages innovative approaches to management, as has been found in northeastern USA, northwestern Europe, and coral reef MPAs (Johnson et al. 2007; Christie and White 2007). All participants felt that training and capacity building to key staff members are important, since this enables them to enhance their skills in the field and thus raise their standards to a certain level so as to perform better. They felt that this has been lacking in staff members of marine parks in Belize.

To date all 12 learning outcomes have been addressed by the local participants. A key positive outcome is that the NGOs TASTE, - TIDE and Friends of Nature have been incorporated into a single NGO, which spans four MPAs in Southern Belize. This means that areas between MPAs which were subject to illegal fishing activity will now be monitored and policed. The merger will enable assessment and enforcement across four different MPAs (Gladden Spit Marine Reserve, Laughing Bird National Park, SCMR and PHMR).

Developing ethical capacity for collaboration in the future (Coffin 2005) will need both resources and iteration over several years, and will involve a delicate balance of 'top-down' and 'grassroots' participation (McDuff 2001; Wescott 2002; Mow et al. 2007) to enable sustainable management. There were two issues that will need addressing in the future: the lack of involvement from the political arena, and 'local' Universities in the study. This paper shows that in Southern Belize conservation partnerships can come together with government to improve ICZM.

Challenges for effective and sustainable co-managed Marine Protected Areas: a case study from the Comoros Islands

C.N.S. Poonian[1,2], M.D. Hauzer[2], C. Moussa Iboura[3]

1) Community Centred Conservation (C3), 17 Northcliffe Drive, London, N20 8JX
2) C3-Comores, BP 8310 Moroni, Iconi, Grande Comore, Union of the Comoros
3) Parc Marin de Mohéli, Nioumachoua, Mohéli, Union of the Comoros

Abstract. Co-managed MPAs must strike a difficult balance between development and conservation objectives and although terrestrial co-management initiatives for parks and reserves have been extensively studied, few evaluations have been conducted of co-managed MPAs. Mohéli Marine Park was the first MPA to be established in the Comoros in 2001. Initially regarded as a model for co-management of marine resources, the MPA is now operating at a vastly reduced capacity following an end to external funding sources. This study assessed current perceptions of local stakeholders of the MPA to evaluate the successes and challenges of the co-management approach. Concern was expressed for the lack of sustainability or alternative livelihoods; inequitable distribution of benefits; exclusion of women; continuing environmental threats and a concurrent lack of enforcement of regulations. MPA managers should carefully consider their options for sustainable sources of finance and lower-cost alternatives to ensure that management activities can continue beyond initial set-up funding. Donors potentially need to rethink policies for initiatives such as MPAs which may be more effectively implemented with a decentralized approach and long-term but consistent funding commitment over at least several years rather than current two- to three-year project cycles that generate visible but short-term results for the implementing team and donors and fail to deliver effective conservation and development outcomes for communities and their marine resources in the long-term.

Key words: Co-management, Mohéli, Comoros, Marine Protected Area, MPA

Introduction

The linkages between human and natural systems and the need for natural resource management approaches that address these linkages are widely recognized (e.g. Mascia et al. 2003). The success of Marine Protected Areas (MPAs) is intrinsically dependent on the behaviour of people in their use of coastal and marine resources (Bromley 1991; Francis et al. 2002; Francis and Torell 2004; McClanahan et al. 2006), thus MPA managers must strike a difficult balance between conservation and livelihood goals. Local stakeholders' perceptions of an MPA are an important indicator of its success and these perceptions will significantly influence their behaviour (Pollnac et al. 2001). Thus the co-management approach, whereby local stakeholders have considerable input into the setup and management of an MPA, has been widely recommended as a means to address these issues. Co-management systems have long been applied to terrestrial ecosystems but have been negatively criticized on their sustainability and appropriateness to local conditions. In a review of 23 such projects in Africa, Asia, and South America, for example, Wells et al. 1992 noted that 'measurable progress has been rare' and they concluded that all projects had failed to meet their stated objectives because 'the critical linkage between development and conservation is either missing or obscure'. However, few independent assessments of the sustainability and effectiveness of MPA co-management have been conducted.

Mohéli Marine Park (*Parc Marin de Mohéli;*Fig. 1), established on 19th April 2001 was initially regarded as a flagship example of MPA co-management, with a committee composed of representatives assembled from ten local villages, government, police and tourism operators (IUCN 2002; Gabrie 2003; Granek and Brown 2005). The MPA was created through the five-year United Nations Development Programme (UNDP) / Global Environment Facility (GEF) funded project 'Conservation of Biodiversity and Sustainable Development in the Federal Islamic Republic of the Comoros' (Project Biodiversity) (IUCN 2004). Currently, the MPA is operating at a vastly reduced capacity following the end of Project Biodiversity, and subsequent end in funding (Wells 2005; C3-Comores 2007, Hauzer et al. 2008). This study

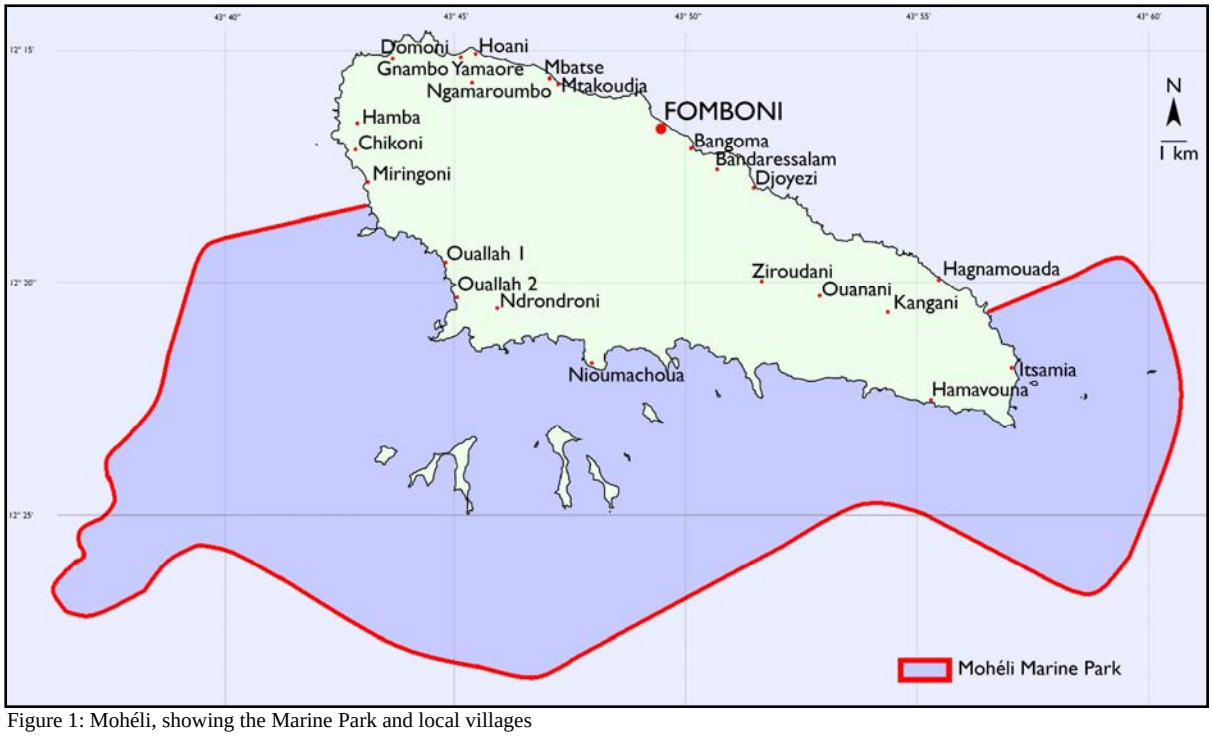

Figure 1: Mohéli, showing the Marine Park and local villages

involved an assessment of the perceptions of local stakeholders of Mohéli Marine Park to assess the challenges that have led to the demise of the once extremely promising co-managed MPA within five years of its establishment.

Material and Methods

Semi-structured interviews were conducted, following guidelines from Bunce et al. 2000, consisting of 12 questions based on six key parameters: (1) basic awareness, (2) value, (3) effectiveness, (4) environmental threats and solutions, (5) stakeholder roles and responsibilities and (6) future aspirations and expectations. The interview was designed to allow for open discussion in a focus group format and relevant follow-up questions were posed during each interview according to participants' responses to the key questions. Participants were selected to encompass the full diversity of stakeholders and male and female focus groups were strictly held separately to ensure that women would feel at ease in voicing their opinions. One male and one female focus group interview was carried out between 10th July 2006 and 20th August 2006 in each of the 10 villages of Mohéli Marine Park: Miringoni, Ouallah 1, Ouallah 2, Ndrondroni, Nioumachoua, Ouanani, Kangani, Ziroudani, Hamavouna, and Itsamia (Fig. 1).

Results and Discussion

Dialogue during the focus group interviews identified a number of positive and negative aspects of Mohéli Marine Park (Table 1). The 11 positive aspects identified corresponded fairly closely with the MPA's original objectives (Gabrie 2003), and participants in all villages believed that the MPA was important. However, the 18 negative aspects identified reveal significant shortfalls in the MPA's management regime.

Problems with sustainability at all levels were identified as the primary negative aspect of the MPA (Table 1). To ensure financial sustainability, Project Biodiversity laid the groundwork for a Biodiversity Trust Fund for the Comoros, including management of protected areas (Bayon 1999). However, a longer time-scale and greater level of capitalization than originally envisaged were required to set up the Fund (Wells 2005).

In the absence of the Trust Fund to cover base management costs, no contingency plan for sustainable funding and no lower-cost alternative for its management, Mohéli Marine Park's financial situation was uncertain following the end of Project Biodiversity in 2003. This was evident to local communities who remarked on the reductions in management effectiveness, activity and levels of enforcement after Project Biodiversity ended (Table 1), and led them to believe that they had been the victims of 'false promises' of the Project as illustrated by the following quote from the Ouallah 1 male focus group: *'Since Project Biodiversity finished, we now say that the words 'Marine Park' do not exist. There has never been follow-up to anything that was*

implemented during the project. With the project, we stopped all of the harmful activities that we were told to stop. However, we saw that we gained nothing, and now, bit-by-bit, we have started engaging in harmful activities again. Moreover, the management of the Marine Park now remains only in the hands of a few individuals, this is the reason that there is more damage occurring now than before, people have lost respect for the Marine Park. To make matters worse, the ecoguards were abandoned as soon as the project finances stopped.'

Table 1: Positive and negative aspects of Mohéli Marine Park identified by focus groups in approximate order of significance (Hauzer et al. 2008)

Positive aspects	Negative aspects
1. Environmental protection and a reduction in environmental destruction	1. Lack of sustainability
2. Increase in fish (size or number)	2. Lack of effective monitoring or enforcement
3. Prohibition of fishing gears	3. Lack of respect of Park personnel for official agreements
4. Increase in environmental consciousness	4. Poor management of equipment
5. Ecotourism	5. Absence of Park personnel
6. Increase in coral cover	6. No positive aspects
7. Exchange and increase in information through international interest	7. Prohibition of fishing gears
8. Infrastructure development	8. Lack of collaboration between Park, external organizations and villages associations
9. Reduction in unemployment	9. Insufficient environmental training, education, and awareness raising
10. Official permission for villages to protect their coastal zone	10. Lack of management of forestry activities
11. Presence of ecoguards	11. False promises of Project Biodiversity
	12. Absence of female participation
	13. Lack of benefits
	14. Lack of motivation
	15. No visible zoning of Park boundaries
	16. Inequitable distribution of benefits
	17. Environment in a worse state since the creation of the Park
	18. Lack of waste management

Lack of effective monitoring or enforcement ranked second for negative aspects of the MPA (Table 1). This issue was raised in eight villages, where respondents stated that a lack of permanent monitoring and enforcement had led to continued turtle poaching and destructive fishing practices. This in itself further de-motivated local communities as those abiding by the regulations were perceived to be the losers whilst perpetrators benefited from freely exploiting resources without due recrimination. The sheer scale, promises and community-conservation rhetoric of Project Biodiversity overwhelmed the local residents, raising their expectations in terms of anticipated benefits. Following the end of funding, communities were unwilling to accept the potential of low-cost, community-driven conservation initiatives, preferring to leave enforcement to the one or two salaried ecoguards who had been appointed by Project Biodiversity from their village. In this way, community motivation for natural resource management was, in some ways, reduced by the creation of Mohéli Marine Park as stakeholders became disillusioned by the lack of activity and tangible benefits following Project Biodiversity.

A lack of transparency in the management of Mohéli Marine Park and inequitable distribution of its benefits were major concerns voiced by local communities (Table 1). Stakeholders felt that benefits were being concentrated in the village of Nioumachoua, which housed the headquarters of the MPA or villages such as Itsamia that host more conspicuous marine attractions such as turtles. As illustrated by Mohéli Marine Park, employment in MPAs can be socially exclusive, in that the benefits accrue to a narrow subset of the local population. Often those employed are primarily from the best educated and motivated of their communities (one of the two senior staff of Mohéli Marine Park was not even Mohélian) rather than from the subsistence-stressed subpopulations that are the most likely to participate in illegal activity in the protected area (Barrett and Arcese 1995). This problem was recognized in 2001, when the gillnet and spear fishers of Nioumachoua expressed their dissatisfaction that Nioumachoua's alternative income-generating scheme (ecotourism facilities) had failed to provide them, the 'victims' of the MPA, with any benefits (Loupy 2001). These views regarding distribution of benefits were a root cause of the ubiquitous feelings of resentment towards the MPA. This dissatisfaction and distrust have clearly contributed to stakeholders' non-compliance with regulations and their unwillingness to actively participate in effective co-management.

It became evident through focus group interviews and discussion with MPA staff that Ndrondroni and Hamavouna were the most socially- and economically-marginalized villages and the also most excluded from its activities. Unsurprisingly, they were also the two villages most notorious for turtle poaching and a lack of compliance with MPA regulations, which was blamed on the communities' Anjoaunais origin (Boinali, pers. comm. 2006). Furthermore, as both villages have poorer infrastructure and services when compared to the other eight villages, they are also less likely to gain any direct benefits from tourism.

Generation of income through ecotourism was one of the key objectives of Mohéli Marine Park (Gabrie 2003) and was recognized by communities as a positive aspect (Table 1). However, tourist arrivals have declined since the MPA was established and communities complained that they were inadequately trained to host tourists and provide guides, accommodation and other services. Local capacity and infrastructure must be considerably improved for ecotourism to provide a significant alternative income on Mohéli (C3-Comores 2008). Although tourism is widely touted in co-management projects as having great potential to generate compensatory income, it has yet to deliver substantial sums as a result of the extreme variability in tourist revenues in response to political turmoil, exchange rate fluctuations and international economic conditions (Barrett and Arcese 1995).

Prohibitions on fishing gear (gillnetting, spearfishing, dynamiting and poisoning) were identified as a constraint by several communities (Table 1). The main concern was the reduction in catch as a result of restrictions, particularly during rough weather. There was also no consensus among communities on the actual effects of these regulations on fisheries yields. Without demonstrated fisheries-enhancement effects, Mohéli Marine Park will be unable to win over fishers who have lost income following gear prohibitions and area closures. Certain communities respected regulations but felt that their efforts were futile because fishers in other villages continued to use banned methods, benefiting from greater catches and a number of fishers felt that they had not received adequate compensation, such as alternative sources of income, alternative fishing gear and/ or training in new fishing techniques.

Project Biodiversity and other initiatives have, in the past, attempted to address these issues through the provision of motorized boats to fishers. However, logistical complications arose concerning the means for many fishers to share a single motorized boat and these projects have only caused conflicts in all villages that were involved in them. Some villages decided that the boat would not be exclusively used for fishing but also for tourism, transporting goods and passengers to other islands. Disputes also occurred if the boat or engine was damaged (Loupy 2001). This lack of positive conservation outcomes from incentive projects reoccurred in almost every village involved in the MPA and a lack of follow-up or formal evaluation of these alternative income generation schemes has made it impossible to learn lessons in order to improve such projects in the future (Malleret 2004).

Conclusion and Recommendations

It is clear that local stakeholders must be adequately informed of, consulted throughout and involved in the effective and sustainable management of MPAs. However, this work shows that in reality, there are pertinent and often overlooked challenges that must be overcome to implement co-management, particularly for large-scale projects. Although the Mohéli Marine Park project was a major, well-funded undertaking which employed international experts throughout the assessment and implementation stages, Mohéli's communities and their natural resources may now actually be worse off, not only materially but also through their altered perceptions of international donors and marine conservation.

The significant funding expended on the Mohéli Marine Park project and evident lack of sustainability after only five years of operation underscore the fact that large amounts of money do not necessarily ensure greater success in fulfilling management objectives. Perhaps more worrying are the unrealistic expectations conferred to local stakeholders from the beginning of the project which could only result in disappointment and disillusionment when promises could not be fulfilled. This now creates a conundrum for future work in Mohéli Marine Park because stakeholders are now unmotivated and wary of external interventions.

In the case of Mohéli Marine Park, tourism was the only large scale alternative livelihood option that was implemented to any extent. Perhaps it would have been more cost-effective to have conducted a detailed market analysis which would have revealed the need for a marketing strategy in tandem with the creation of tourism infrastructure. Now, although the buildings exist, without funding or the ability to market their tourism product, local communities will find it difficult to gain any revenue from tourism (C3-Comores 2008). Had sufficient consultation taken place with the fishers, the most relevant stakeholder group, alternative fishing gears and relevant training sessions could have been held to help offset losses in income due to area closures and gear restrictions. Inclusion of women in separate consultations would have revealed their significant roles in household income generation and provided options for developing their artisanal industries to offset losses in household income through restrictions in fishing activities. Such activities would be less reliant on external factors than tourism and thus potentially more sustainable in the long-term.

Donors need to pay more attention to long-term outcomes when considering a co-managed MPA project, and spreading available funding over five or ten years would potentially allow for more equitable distribution of benefits as management is adapted as

the MPA develops. This is particularly significant in cultures where effective and inclusive decision making processes work at a much longer time scale than the donor's project schedule. Experience has shown (Borrini-Feyerabend et al. 2004) that to achieve success, stakeholder-inclusive conservation projects often operate more effectively at small decentralized scales with small infusions of money over longer project terms. This smaller-scale approach to marine resource management on Mohéli may have allowed for a sustained management programme, better adapted to local capacity with reduced levels of conflict between the 10 villages. The negative correlation between the size of conservation projects and their effectiveness and success is supported by a report on GEF projects that determined that they had generally been a major failure except for the Small Grants Programme (Horta et al. 2002).

Acknowledgement

Development of a strategy to guide the use of remotely sensed information in the management of coral reef environments

C.M. Newman[1], E. LeDrew[1]

1) University of Waterloo, 200 University Avenue West, Waterloo, Ontario, N2L3G1, Canada

Abstract. We have developed a strategy to guide the use of remotely sensed information in the management of coral reef environments in developing countries. The strategy includes development of a habitat map using satellite imagery, investigation of stakeholder receptivity to the habitat map, linking management issues to specific habitat types, and context-appropriate illustration of mapped data. The strategy was developed using IKONOS 4x4 m multi-spectral satellite imagery and interview data from dive operators, fishermen, and managers of Bunaken Island, Indonesia. The potential for this strategy to address coral reef management issues is wide-reaching and strongly depends on interaction between scientist and manager.

Key words: Remote Sensing, Local Knowledge, Coral Reef Management, IKONOS.

Introduction

Within the field of coral reef remote sensing, researchers have for many years been developing coral reef habitat maps (Riegl and Purkis 2005; Mumby et al. 2004; Andrefouet et al. 2003; Maeder et al. 2002). Each map contains a collection of habitat types, which are defined by their combined structural framework and biological composition (Veron 2000). These combined characteristics permit identification and delineation of the habitats within high-spatial satellite imagery (Mumby et al. 2004; Holden 1999; Knight et al. 1997). Within the last decade, these habitat maps have, in some places, contributed to coral reef management. This should be expected from habitat maps that delineate management-relevant information.

Until recently, however, there has been little interest in utilizing coral reef habitat maps for management in less-developed countries. There are many reasons for this: cost, available expertise, and general knowledge about the applicability of the information. In addition, there have been few opportunities for local communities to use such maps mainly because these communities have been removed from decision-making processes. In Indonesia, however, recent decentralization of the government has brought about increasing decision-making power to local levels, especially to small island communities (Nickerson and Olsen 2003; Erdmann et al. 2004). In the northern regions of Sulawesi, small island communities can now influence, more directly, management efforts (Erdmann et al. 2004).

If remote sensing-based coral reef habitat maps are to contribute to these management efforts, logically, it is necessary that the habitat maps illustrate information that is relevant to decision-makers. To this end, decision-maker knowledge must be integrated to the mapping procedure. In this study, we present a procedure that could be used to integrate decision-maker knowledge, to link this knowledge to the information in the habitat map, and to illustrate those habitats that are relevant to management. This procedure transforms habitat maps into 'management maps'.

Materials and Methods

This study involved the development of stages that together resulted in the development of management maps. To develop these stages, both the remote sensing and social contexts were considered. It was assumed that implementation of the stages would be facilitated by a remote sensing scientist. Therefore, we assume that the remote sensing scientist must engage in active research and collect and assess qualitative data. This means that the scientist is challenged to collect both physical and social science research and to integrate the information in an appropriate way.

Study Area

The study site for this research was Bunaken Island, which lies off the Northeast point of Sulawesi, Indonesia near the city of Manado. The island is surrounded by well-defined tropical coastlines, which

include a tidal flat, reef crest, reef slope, and reef wall. In some areas, the tidal flat extends up to 0.5 km from the shoreline. At the reef wall, the water depth drops down to the continental slope at 1840 metres. In the waters surrounding Bunaken Island, there are a minimum of 58 general and sub-genera of corals and approximately 2,000 species of fish (Mehta 2000).

According to the 2005 consensus there are three villages on the island of Bunaken: Alung Banua (population: 807), Tanjung Parigi (population: 610), and Bunaken (population: 2000). The people living in the villages are descendents of fishers who used Bunaken Island as a stopover location before heading out to sea. Dive operators also occupy the island and, at the time of this study, 15 are established and 11 are operating.

Bunaken Island was the first island in Bunaken National Park to be assigned a zonation system. The system includes three primary zones: core conservation zone, tourism use zone, and village use zone and is one of five islands situated within Bunaken National Park (BNP), which is 89,056-hectare in size.

In addition to the zonation plan, coral reef management activities include the placement of ecoreefs in shallow water coastal areas that have experienced considerable blast fishing. The coral reef crest environment nearby Alung Banoa Village and Fukui dive site now hosts over 60 ecoreefs that were provided by Seacology and implemented by NRM III personnel, local fishers and dive operators. An additional coral reef management activity that is gaining momentum is reef monitoring. Several dive operations have added a monitoring component to the Open Water, Rescue Diver, Dive Master, and Dive Instructor courses that involves quantitative assessments of health at various dive sites. Other management efforts include monitoring grouper species at identified Spawning Aggregation Sites (SPAG).

Research Methods

The research methods in this study are grounded in the broad methodological fields of remote sensing habitat map development and community participation in project development.

Qualitative data gathering tools included informal interviews, focus groups, and participant observation. The tools were selected using assistance from on-site researchers and from the Socioeconomic Manual for Coral Reef Management (AIMS, 2000). The qualitative data collection processes followed the principles laid down in Participatory Rural Appraisal (PRA) methodologies (Chambers and Guijt, 1998).

Based on the social context and the information available by the remotely-sensed habitat map the following four stages were identified: the first stage is to develop a habitat map; the second stage is to acquire stakeholder feedback to the habitat map; the third stage is to link the stakeholder feedback with habitat data; and, the fourth stage is to illustrate the linked information using stakeholder-identified cartographic elements. Each of these four stages was conducted in sequence and is described below.

Stage One: Development of a habitat map

First, two 4-metre multispectral and 1-metre panchromatic IKONOS satellite images of Bunaken Island were captured for July 7th, 2001 and June 6th, 2004. Both images were acquired with full 11-bit radiometric resolution and at 18-degrees off-nadir angles. Both images were acquired under conditions of light haze, < 20% cloud cover, and minimal surface water roughness. Image preprocessing included radiometric and geometric corrections, which were conducted by Space Imaging.

Field data included a library of ground observation points that were collected in both 2001 and 2004 for the purpose of sea-truthing the satellite images. A ground observation point represents one point on the ground, covering an area of 4 x 4 metres, from which geographical coordinates, water depth, substrate type and cover, and photographs were collected. Most points were selected randomly throughout all geomorphological zones (reef flat, reef crest, and reef slope) and all management zones (core, tourism, and general). Some points lie at half-metre intervals along transects that were placed over areas of interest, beginning at the shoreline and extend to the reef crest. Along transects, video surveys were conducted.

Initially, both images were georeferenced using GPS measured control points. The two images were then compared to each other. Areas of land, clouds, boats, and deep water outside the reef crest were then masked out. A basic atmospheric correction was applied to the imagery that involved sampling a large number of pixels from the 'deep water' area. A depth correction was then carried using Lyzenga's model.

For each image, over 600 ground observation points where then used to develop training areas, encompassing each of the six classes in all geomorphological zones. The training areas were input in a supervised maximum likelihood classifier. The final habitat map classes included coral (< 5m deep), coral (5-15 m deep), sparse seagrass, dense seagrass, silt, sand. The resulting habitat maps had overall classifications accuracies of 78% (2001) and 81% (2004).

Results

Stage Two: Investigation of stakeholder receptivity to the habitat map

The objective of stage two is to investigate stakeholder receptivity to the habitat map. Using informal interviews, focus group discussions, and participant observation techniques stakeholder receptivity to map content, map presentation, and map applicability to current and future management projects was investigated.

Qualitative data were collected in 2004 and the total number of respondents interviewed was 36, the total number of focus group discussions was 5, and participant observation was conducted regularly throughout the field period.

The following results were established. Generally, stakeholders agreed that a habitat map should contain no more than three to four habitats types. If the map contains more habitat types it is unlikely to be used. A habitat map should contain only those habitats that are relevant to each stakeholder group. In terms of map presentation, a habitat map should contain (1) the local names of the habitats, (2) land, deep water, and local references, and (3) standard cartographic elements such as a north arrow, scale, title, and legend that are written in the local language. In terms of map applicability, the habitat map should contain only those habitats for which known linkages between habitat and management issue are well know and established within the community.

Stage Three

The objective of stage three is to conduct an objective and systematic approach to linking management issues identified in stage two with habitat types identified in stage one. The researcher and research assistants deconstructed the feedback by using heir knowledge of the physical and social environments, and identified a degree of association between indicator and habitat. The 'degree of association' provides a means of quantitatively assessing the strength of association between indicator(s) that were identified by stakeholders and habitat(s) that were delineated in the IKONOS satellite imagery.

Results include a list of indicators, identified by stakeholders that describe the feature of interest such as a particular coral or fish species. The location and time period of interest was also identified. Results also include a list of habitats, which were delineated in the habitat map, that can be matched to the indicator. Then, a degree of association was calculated for all matches and results illustrate that 66% of the time, the habitat map contains habitat types that are relevant for addressing management questions.

Stage Four

A multitude of techniques is available for applying cartographic elements to a habitat map; however, the methods presented here focus on integrating general structure, reference features, habitat type illustration, and map format. Stakeholders created these categories: each category was identified as 'critical' to recognition and understanding of the mapped information. The categories were then used as a guide in the development of management maps.

Features of interest to each stakeholder group were highlighted or polygons were drawn around the feature. The legend of each map included the location of docks, villages, places of worship, and markets. A permanent feature in every map was the location of dive sites and the location of management zones. More specific features of interest, identified in stage two, were applied to each respective stakeholder map.

Discussion

It is important to note that throughout each field season for this research several key themes emerged.

(1) Tradeoff between cost and scale. For example, the fishermen on Bunaken Island are familiar with the spatial location of seagrass and, in many places, how the concentration of seagrass has changed through time. The cost of having this same information illustrated in a temporal management map at a fine spatial scale may far exceed what fishermen can contribute and may far outweigh the real use of the information. A more cost effective approach may involve acquisition of free satellite imagery, with coarse spatial resolution, investigation of seagrass concentration change using multiple images, and development of a temporal management map that illustrates only those regions with a considerable gain or loss in seagrass. This method provides the same information as is provided by a change detection analysis with IKONOS satellite imagery, however, the cost of the imagery is removed from the overall budget. Generally, in the future, it will be important to assess whether the cost of acquiring fine spatial scale information outweighs the cost of the imagery.

(2) Communication between scientist and manager. Considerable effort was made by the researcher to learn the local language and local terminology that is used to describe the coral reef environment. Though, at times, simply knowing the terms was not enough to capture the context and essence of the message communicated by the manager. To enhance communication, shared experiences (scientist-manager) are critical. Workshops, field trips, and joint presentations create a collaborative environment, one in which both scientist and manager can ask questions of each other and work together to target the same objective/interest. Field trips, for example, are an excellent opportunity to expose the manager to the

environment in which remotely-sensed field data are collected. Explanations on how the habitat data are collected and measured can be demonstrated, while in exchange the manager can ask questions and provide stories or explanations for certain locations or the state of specific portions of the coral reef environment.

(3) Community-based research approaches. An important key theme in this research is that community-based research approaches warrant attention, investigation, and inclusion in the strategy. To both capture and utilize the local processes of environmental management, it is critical to know how community-based research is employed, what information is deemed relevant and useful, and how the information is used. Without knowledge of these factors, it is nearly impossible to integrate foreign information or processes. However, identification of this information is challenged by communication and physical barriers. In some instances, meetings are closed to the public, to foreign researchers or students, or to personnel that are not directly involved in a project. During such instances, effort must be made to attend, to provide some skill or product in exchange for attendance. Because, it is often during such meetings, that decisions are made and the process of how these decisions are made is critical information.

3) Conservation International-Philippines, # 6 Maalalahanin Street, Teachers Village, Diliman, Quezon City, Philippines

Abstract. Few efforts have been directed at evaluating the biophysical, socioeconomic and governance effectiveness of marine protected areas (MPAs) based on MPA objectives and management actions. This paper describes the process, indicators and lessons learned in developing monitoring and evaluation (M&E) programs for two MPAs in the Philippines: the Tubbataha Reef National Park and the Coron Island Ancestral Domain. The Tubbataha reefs, a World Heritage Site, covers 33,200 hectares of offshore reefs with exceptionally high biodiversity. Coron Island covers 22,284 hectares of ancestral (*Tagbanua* tribe) land and waters. The process to develop monitoring programs included: stakeholder consultations and consensus on indicators; creation of an monitoring team; data collection; information sharing; capacity building of monitoring team; and, institutionalization of management structure. Biophysical indicators measure the protection of marine species and habitats. Socio-economic indicators identified largely measure the economic status of the coastal communities in terms of household occupational structure. Governance indicators identified are mostly process indicators such as existence of a decision-making/management body and clearly defined enforcement procedures. Key lessons learned include: capacity building is a major bridge for overcoming technical difficulties in undertaking M&E functions; developing partnerships between local government and local stakeholders helps in accessing relevant information; and, a multi-disciplinary approach provides a comprehensive assessment for measuring the success of MPAs.

Key words: Coron Island Ancestral Domain, marine protected areas, monitoring, Philippines, socioeconomic, governance, Tubbataha Reef National Park

Introduction

In the Philippines, few efforts have been directed at monitoring and evaluation of marine protected areas (MPAs). The lack of adequate socioeconomic data and analysis of these information to provide concrete correlations between management actions and desired conservation outcomes of MPAs have not been well documented. This situation, in turn, weakens the support for establishing and maintaining MPAs. Without an effective monitoring and evaluation (M&E) program, tracking progress and providing feedback to MPA management cannot be achieved.

Monitoring and evaluation are distinct management functions, yet these are interactive and mutually supportive activities. M&E supports accountability in the use of resources and informed decision-making for corrective actions and to reinforce early signs of success. Various regulatory and management entities independently conduct M&E programs, which has resulted in duplication of efforts. Additionally, these entities often fail to present monitoring results in a form that is useful for shaping policy, resulting in the lack of a feedback loop that would permit periodic evaluation of the management effectiveness. Failure to effectively use information to undertake action and policy interventions leads to continued inefficient use of resources, and further deterioration of biodiversity in protected areas.

The purpose of this paper is to present the process in developing an M&E program to assess the effectiveness of management regimes for the Tubbataha Reef National Park (TRNP) and Coron Island Ancestral Domain (CIAD). These two MPAs are extremely high priority coral reef areas in Palawan Province, Philippines. The M&E indicators are described, as well as the lessons learned. This paper

forms part of the project of Conservation International–Philippines titled, 'Development of Management Monitoring and Evaluation Programs for Two Marine Protected Areas in Palawan, Philippines', funded by the U.S. National Fish and Wildlife Foundation.

Methods

Figure 1 presents the MPA location. Both protected areas are nationally and globally significant, not only because of their high levels of biodiversity, but also due to their high economic and social benefits. The TRNP covers 33,200 ha of offshore reefs in the midst of the Sulu Sea. It was established as a national marine park in 1988, and was designated a UNESCO World Heritage Site in 1993. Marine biodiversity is exceptionally high with at least 417 fish species, 372 coral species, 23 seabirds and eight species of marine mammals. These include a critically endangered sea turtle, an endangered marine mammal, seabird and sea turtle, and two vulnerable giant clams.

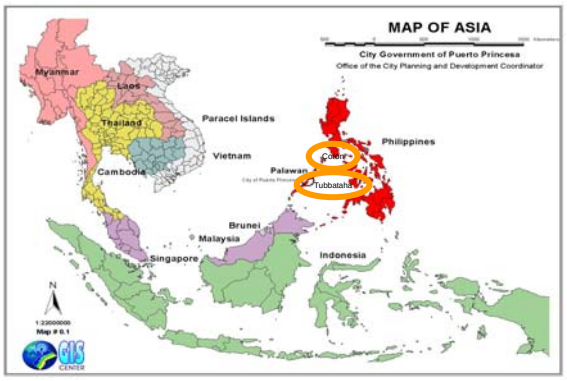

Figure 1: Location map of Tubbataha Reef National Park and Coron Island Ancestral Domain, Philippines.

The area of CIAD is within the Calamianes group of islands in northern Palawan Province, covering an area of 22,284 ha of ancestral land and waters. A unique marine biogeographic zone, CIAD harbors approximately 462 coral species, with at least 30 more new species recorded, and more than 700 species of fish. What makes this MPA unique is its direct management by indigenous peoples called *Tagbanwa*. A Certificate of Ancestral Domain Claim, a legal instrument given to indigenous groups to gain security of tenure over their ancestral land and waters, was awarded to the *Tagbanwa* tribe in June 1998.

Six key intricately-related and overlapping activities were undertaken to develop the M&E programs for the two MPA's. First, a series of multi-stakeholder consultations were undertaken to develop a consensus on identifying and selecting appropriate biophysical, socioeconomic and governance indicators. This involved participants from agencies and institutions that have mandate - in one form or another - in managing the two MPAs. This resulted in the formulation of an action plan for developing the M&E program strategy, including implementation and management arrangements. Second, the M&E team was created. This team was comprised of representatives from regulatory, management and research/academic bodies, other environmental groups, and indigenous peoples that were conducting monitoring programs or planning monitoring programs within the two protected areas. The team's main output was the design of the M&E program. Third, data collection was undertaken. It involved literature review, secondary analysis and primary data gathering. This was done as a collaborative endeavor among the participating institutions and stakeholder groups. Fourth, there was sharing of information collected. Primary data generated were analyzed and synthesized with the existing data and literature. This was followed by trainings as part of capacity building for the M&E team and stakeholders were conducted. Training exercises included topics on M&E concepts, rationale, socioeconomic survey methods, analysis and interpretation of results. Lastly, the institutionalization process for the implementation of the M&E program was initiated. This included the designing and agreement on the M&E proposed management structure.

Results

Three key result areas are presented. These relate to the following: (1) selection process for M&E indicators; (2) sample of datasets generated for indicators; and (3) rating for the relevant indicators.

Selection of the M&E indicators was based on the MPAs' management objectives contained in their respective plans.[1] The management objectives of both MPAs cover relevant biophysical, socioeconomic and governance dimensions (Table 1). Typical to most protected areas, these MPAs are trying to achieve an array of human and natural resources-related objectives. Based on these management objectives, coupled with intensive consultations with relevant stakeholder groups, the M&E indicators were selected. CIAD had 22 indicators (Table 2), while TRNP had 20 indicators (Table 3).

Table 1: Examples of biophysical, socioeconomic and governance objectives contained in management plans of Tubbataha Reef National Park and Coron Island Ancestral Domain.

Objectives	Tubbataha Reef Management Plan	Coron Ancestral Management Plan
Biophysical	To protect biological diversity and ecological processes	To protect and rehabilitate ecosystem function, communities,

[1] The TRNP already had a well established management plan. For the CIAD, this project assisted Coron management in drafting the Coron Ancestral Domain Sustainable Development and Protection Plan.

Objectives	Tubbataha Reef Management Plan	Coron Ancestral Management Plan
	from unnatural threats and human impacts.	habitat quality, species and gene pools.
Socioeconomic	To increase income potential from ecosystems targeted for conservation.	To stabilize or diversify household occupational and income structure through reduced marine resource dependency.
Governance	Ensure stakeholder participation and representation.	To ensure compatibility and enforceability between legal and local arrangements and improve the application of laws and regulations.

Table 2: Indicators for assessment of Coron Island Ancestral Domain management effectiveness.

Biophysical indicators	1. Focal species abundance 2. Focal species population structure 3. Composition and structure of the community 4. Type, level and return on fishing effort 5. Area showing signs of recovery 6. 6. Area under no or reduced human impact
Socioeconomic indicators	1. Local marine resource use patterns 2. Level of understanding of human impacts on resources 3. Household income distribution by source 4. Local values and beliefs about marine resources 5. Perceptions of local resource harvest 6. Household occupational structure 7. Number of tourists
Governance indicators	1. Level of resource use conflict 2. Existence and adequacy of enabling legislation 3. Local understanding of MPA rules and regulations 4. Level of stakeholder participation and satisfaction in management 5. Level of stakeholder participation in surveillance, monitoring and enforcement 6. Number of local legislations adopting national policies 7. Effective MOA among implementers of the ADSDPP

Table 3: Indicators for assessment of Tubbataha Reef National Park management effectiveness.

Biophysical indicators	1. Focal species abundance 2. Focal species population structure 3. Habitat distribution and complexity 4. Composition and structure of the community 5. Type, level and return on fishing effort 6. Water quality 7. Area showing signs of recovery 8. 8. Area under no or reduced human impact
Socioeconomic indicators	1. Local marine resource use patterns 2. Level of understanding of human impacts on resources 3. Perceptions of non-market and non-use values 4. Household income distribution by source 5. Number and nature of markets 6. Distribution of formal knowledge to community
Governance indicators	1. Level of resource use conflict 2. Existence of a decision-making and management body 3. Existence and adoption of management plan 4. Existence and adequacy of enabling legislation 5. Availability of and allocation for MPA administrative resources 6. Degree of interaction between managers and stakeholders 7. Clearly defined enforcement procedure 8. Degree of information dissemination to encourage stakeholder compliance

For the TRNP's eight biophysical indicators, the first four measure how much of the marine resources, biological diversity, individual species and habitat is protected. Species abundance (diversity) is defined as the number of individuals of a particular species found to occur within and outside the MPA. A focal species is an organism of ecological or human value that is of priority interest for management through the MPA. Data from the literature indicates that the seabirds' breeding populations have been maintained over the years (CI-Philippines, 2006).

Three examples for socioeconomic indicators are provided. The number of tourists engaged in diving has fluctuated over the years but shows an increase from about 500 tourists in 1989 to over 800 tourists in 2003 (Figure 2). Compared to other dive destinations, the trip to the TRNP is only feasible for about three months a year (March-May) due to weather conditions. The people of the Cagayancillo municipality, by virtue of political geography, are the TRNP's local stakeholders. Their dependence on marine resources (eg, fishing) has declined by over 50% since the establishment of the TRNP (Figure 3). The park's use values are largely generated through tourism (Figure 4). The TRNP is one of the most highly regarded diving destinations in the world.

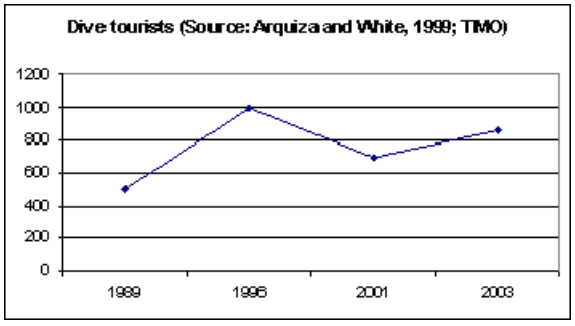

Figure 2: Local marine resource use patterns in terms of dive tourism in Tubbataha Reef National Park.

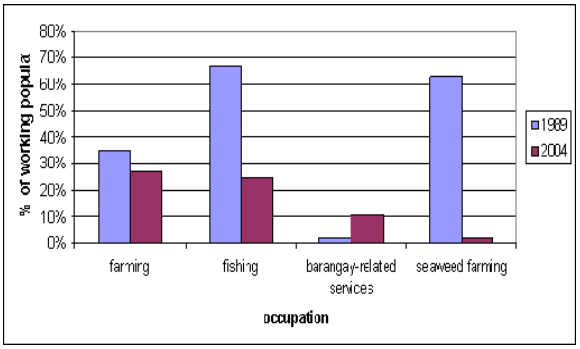

Figure 3: Household income distribution by source in Tubbataha Reef National Marine Park.

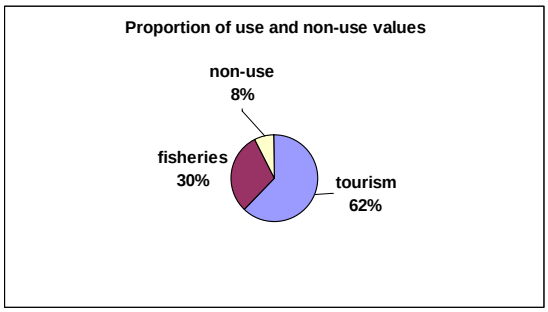

Figure 4: Perceptions of non-market and non-use values in Tubbataha Reef National Marine Park (Estimated value at US$ 64 million)

Two examples on the socioeconomic and governance indicators are provided in the case of CIAD. The stakeholders' perceptions of local resource harvest and opinions on level of resource use conflict are provided in Table 4 and Table 5, respectively. The people perceived that their yield from the fisheries is decreasing. Since smaller fishes are caught now, it implies biological overfishing. Conflicts appear to be escalating and appropriate measures are needed to resolve them. Legally, the municipal government largely operates through the Local Government Code of 1991 while the local *Tagbanuas* manage their ancestral domain through the Indigenous Peoples Rights Act of 1997. Although the municipal council did not dispute the evidence that the Calamianes Tagbanuas have held since time immemorial possession of CIAD areas, it claims also to have rights to the ancestral land and waters occupied by the indigenous peoples.

Table 4: Perceptions of local resource harvest by stakeholders at Coron Island Ancestral Domain.

Compared to 10 years ago	Response
Has the available target species changed?	Several species can no longer be seen like big eye scad, rabbit fishes, and siganids
What is the quantity of available target species?	A lot less- Before, fishing half a day yields 5 kg but now, fishing one day yields 2 kg. Before, 4 hours of fishing for fish yields 6-8 kg but now, zero.
Has the size of target Species changed?	Smaller fishes are caught now

Table 5: Opinions about level of resource use conflict by stakeholders at Coron Island Ancestral Domain.

Existing data	Data source
• Coron Municipal Council filed more than 14 municipal resolutions opposing the ancestral domain claim • Cited the interest of the burgeoning tourism industry, large-scale commercial fishing	Local NGO report
Primary data	**Data source**
• Small-scale fishers conflict among commercial fishers, tourist operators, local government	Key informant interview and stakeholder consultation

The suites of indicators are presented in summary format. Qualitative ratings are provided as follows: '+' for positive; '-' for negative rating; '0' for no change rating; and '?' for indeterminate rating due to insufficiency of information. As part of M&E process, the stakeholder groups and representatives of site M&E teams agreed on the above ratings and applied them in their preliminary assessments of their respective MPAs. This was undertaken during several stakeholder consultation workshops where stakeholder participants discussed and agreed on final appraisal of each indicator against baseline data

The biophysical objective in TRNP is 'to protect biological diversity and ecological processes from unnatural threats and human impacts'. Since most of the summary ratings for biophysical indicators are positive, it implies that the above objective has been largely met (Table 6). Except for 'perceptions of non-market and non-use values' which is rated indeterminate due to limited information, the rest of the socioeonomic indicators are all positive (Table 7).

Table 6: Summary rating for biophysical indicator on focal species abundance and diversity in Tubbataha Reef National Park.

Appraisal Against Baselines		Remarks
Seabirds:	Diversity +	Monitor breeding species only
	Abundance +	
Turtles:	Diversity 0	No data to determine abundance
Cetaceans:	Diversity ?	Cannot directly attribute to management effectiveness; 2004 data of TRNMP set as baseline.
Fishes:	Diversity +	1997 data of WWF set as baseline.
	Biomass +	
	Density +	
Indicator Fish:	Biomass +	Pomacentridae (negative)
	Density +	
Top Predators:	?	No sufficient data; Use 2005 data as baseline.

Table 7: Summary rating for socioeconomic indicators in Tubbataha Reef National Park.

Socioeconomic Indicators	Appraisal	Remarks
1. Local marine resource use patterns	+	Adapt 1986 baseline data
2. Level of understanding of human impacts on resources	+	Adapt 2004 baseline data
3. Perceptions of non-market and non-use values	?	Adapt 2004 baseline data; Uncertain trend
4. Household income distribution by source	+	There was diversification of income source and an increase in per capita
5. Number and nature of markets	+	Cagayancillo benefited from dive fees; stable price of seaweed
6. Distribution of formal knowledge to community	+	Need to examine impact of IEC materials; need to diversity IEC media (eg;TV, radio)

In the case of governance indicators, all are rated positively, except the indicator on 'availability and allocation for TRNP administrative resources' (Table 8).

Table 8: Summary rating for governance indicators in Tubbataha Reef National Park.

Governance Indicators	Appraisal	Remarks
1. Level of resource use conflict	+	There is positive effort towards reduced conflict (local fishers); emerging conflict between energy and fisheries
2. Existence of a decision making management body	+	Baseline data from Tubbataha Management Office, 2002
3. Existence and adoption of a management plan	+	
4. Existence and adequacy Of enabling legislation	+	
5. Availability and allocation for TRNMP administrative resources	-	Funds were adequate due to external funding through UNDP-GEF 2000-2004; Funds utilized in 2002 were from the dive fee collection
6. Degree of interaction between managers and stakeholders	+	
7. Clearly defined enforcement procedures	+	
8. Degree of information dissemination to encourage stakeholder compliance	+	Use radio for information dissemination.

Discussion

Developing and sustaining the operations of M&E programs for MPAs are difficult endeavors. This component of MPA management is not as well developed, when compared to other established components, such as information and education campaigns or law enforcement.

Attempts were made to come up with quantitative measures of success, which are beyond anecdotal evidences. Some substantial insights may be generated from this study. For TRNP, many of the indicators are rated positive based on trend or compared to an agreed baseline. Particular attention, however, must also be given to the allocation of financial and administrative resources.

In the case of CIAD, the fishery resources is apparently dwindling. If more people perceive that target species is decreasing, then this is not favorable and implies that more effort needs to be directed at determining and addressing the cause of this declining trend.

Several lessons were also learned in the course of developing the M&E programs for these MPAs. First, active involvement of the local government units is crucial for effective MPA management. Secondly, capacity building for the management staff and participating agencies is a major bridge for overcoming technical difficulties in undertaking M&E functions. Linking with local researchers and academic institutions is important. Thirdly, developing partnerships between the local government and the local stakeholders helps in accessing relevant information. Lastly, a multi-disciplinary approach, utilizing relevant mix of indicators, provides a more complete assessment for measuring the success of MPAs.

Green Fins-Thailand: Coral Reef Conservation in the Face of a Tourism Epidemic

K. Kosavisutte[1]

1) Phuket Marine Biological Center 51 Moo 8 Sakdidej Rd., Muang District, Phuket 83000 Thailand

Abstract. In Thailand, reefs along Andaman and Thai Gulf coast cover 160 square kilometers. Only sixteen sites are designated National Parks. Over 670 dive, snorkel tour and boat operators bring an estimated million guests to visit primary dive sites during the six month high season each year. Currently, there are many problems contributing to reef destruction. The Government lacks infrastructure planning for the growing tourism industry and promotes reef tourism without conservation and resource management. National Parks possess insufficient human resources. Dive and tour operators lack an understanding of reef ecology and use the natural resource for business only. The popularity of reef tourism is ever increasing and this lack of management is causing devastation on the reefs of Thailand. The Green Fins mission is to protect and conserve coral reefs by establishing and implementing environmental-friendly guidelines for divers. We actively seek out dive operators, introduce our program, educate and encourage operators to become members. We also arrange for individual members to participate in activities such as cleanups, reef monitoring, or exhibitions. Members receive certificates and materials to promote good diving practice. To renew membership, operators are assessed yearly based on Green Fins Code of Conduct criteria. We use this network to promote sustainable dive and snorkel tourism industry. We hope that in the future, tourists will begin to ask operators whether they are Green Fins members and choose to dive with Green Fins friendly operators. In this way, the Green Fins Program will establish a network of active conservationist divers and snorkels, spreading the word quickly and being an effective voice for positive change in the dive and snorkel tourism industries. We hope that someday, our methods will be applicable to other heavily toured nations facing similar problems.

Key words: Environmental-friendly, Sustainable, Network, Monitoring, Awareness

Introduction

Currently, there are many causes that contribute to coral reef destruction. The rapidly growing tourism industry has a negative impact on the reefs. That is why the Green Fins Program has been established in four countries, namely Thailand, Indonesia, Malaysia and the Philippines by the Coordinating Body on the Seas of East Asia (COBSEA). COBSEA is one of UNEP's Regional Seas Programs. In Thailand, Green Fins is implemented by the Phuket Marine Biological Center (PMBC), Department of Marine and Coastal Resources.

Methods

The Green Fins mission is to protect and conserve coral reefs by establishing and implementing environmental-friendly guidelines for divers. We actively seek out dive operators, introduce our program, educate and encourage operators to become members. Members receive certificates and materials to promote good diving practice. To renew membership, operators are assessed yearly based on Green Fins Code of Conduct criteria which consist of environmentally friendly standards for dive operator. We use this network to promote sustainable dive and snorkel tourism industry.

Green Fins Thailand has also developed a Reef Watch method to encourage divers and operators to help monitor their reefs. It is a one-dive-one survey method to record the health of coral reef that even snorkelers are able to practice. In addition, dive operators may provide this program to customers as a form of educational awareness as opposed to purely leisure. Data can be uploaded online via the website www.greenfins-thailand.org which will be input into a National Database. We promote IYOR activities by encouraging Tour Operator Members to adopt a reef in which members can choose different dive sites to monitor with a minimum of 2 data entry per year. We aim to have members attend these activities in all areas nationwide so that reefs and dive sites are monitored as much as possible.

Results

Currently we have 90 Operator Members and 302 Individual Members mainly from 6 provinces along Andaman Coast without recruiting for new members. We also have 211 Reef Watch data forms submitted by members. We try to work closely with them to actively promote Green Fins for sustainable diving tourism industry. We also arrange for operator members and individual members to participate in activities and encourage Operator Members to organize their own activities with tourist and local communities. Activities that Green Fins organize to raise awareness are

- Exhibition at Thailand Travel & Dive Expo
- Adopt-A-Reef, Adopt-A-Beach program
- Photo Contest topic on "Marine Litter the Sea and the Coast"
- Recycle Art Workshop from garbage washed ashore
- Organize International Coastal Clean Up
- Organize the IYOR meeting with Dive Operators, and divers

Discussion

We primarily work in management, monitoring and education areas. Assessment method could help select the green dive operator through the continued close contact with members. In the long run, Green Fins will become recognized as a standard to certify green dive operators. Raising awareness and education is also essential for people to understand why the guideline are applicable. By doing so, Green Fins needs more funding to support volunteers, to help coordinate with existing members, and to continue to recruit new members and expand into other dive location sites. Green Fins-Thailand can also be further developed for snorkel tour operators, and for raising the awareness of local people. All dive sites need full time attendance from coordinator, with a long term establishment of voluntary programs in order to see satisfactory results.

Conclusion

For sustainability of the Green Fins program, we are in a process of registering Green Fins to become an Association in order to expand already existing projects within the area, and raise funds from private sector groups to support a full time coordinator. We hope that in the future, tourists will begin to ask operators whether they are Green Fins members and choose to dive with Green Fins' friendly operators. In this way, the Green Fins Program will establish a network of active conservationist divers and snorkels, spreading the word quickly and being an effective voice for positive change in the dive and snorkel tourism industry. We hope that someday, our methods will be applicable to other highly toured nations facing similar problems.

Restoration of threatened *Acropora cervicornis* corals: intraspecific variation as a factor in mortality, growth, and self-attachment

A. Bowden-Kerby

Coral Gardens-Living Reefs, Counterpart International, P.O. Box 4649, Samabula, Fiji Islands

Abstract. The potential of farming *Acropora cervicornis* corals to generate material for restoring the species to Caribbean reefs was investigated. Coral colonies from both high and low energy areas were sampled, to determine the relative importance of intraspecific variability and source environment on mortality, growth, branching density, and self-attachment. Isolated *Acropora cervicornis* thickets, were sampled, half from the reef front and half from the back reef. Each thicket sampled was assumed to be of a single coral genotype. Replicate fragments were sampled from each thicket and transplanted to wire frames located in shallow back reef areas <2m deep, on five reefs in the La Parguera reef system, Puerto Rico. Results at one year indicate that coral genotype is a highly significant factor for all of the variables studied, with up to a six-fold difference in relative growth based on genotype alone. Back reef and reef front populations of *A. cervicornis* corals differed significantly in relative growth, branch diameter, and attachment ability even after growing together for one year, suggesting a genetic basis to morphology and adaptation to their original environment. Frame culture was an effective method to produce second generation stock, with annual growth rates often over ten fold.

Key words: *Acropora cervicornis*, coral restoration, coral farming, coral gardening.

Introduction

Acropora cervicornis is composed of low-diversity, predominantly clonal populations of corals maintained by asexual fragmentation with clones shown to span distances as great as 30-50 m (Bothwell 1981; Neigel and Avise 1983). The clonal nature of the species has major implications for the restoration of this threatened Caribbean coral (Bowden-Kerby 2001a; Bowden-Kerby et al. 2005).

While remnant *A. cervicornis* populations may be predominantly composed of a single genotype and thus unable to effectively reproduce sexually (Bowden-Kerby 2001a), the fact that the species easily fragments to create clonal populations creates the potential for developing low-tech restoration methods modeled after and accelerating these natural fragmentation processes (Bowden-Kerby 2001a, 2001b). Alternatively, the highly clonal nature of the species might also present unforeseen challenges, particularly for this "generalist" species which occurs over wide environmental gradients, as each genotype may be highly adapted to a narrow range of environmental tolerances. It can be assumed that a particularly abundant genotype would be well-adapted to the set of environmental conditions where it occurs and that long-term selective processes would eliminate maladapted coral strains over time while favoring particular genotypes. If the survival or growth of coral transplants is strongly related to the original environment of the corals, closely matching the source environment of the corals with that of the transplant site would be important to long-term success.

This study focused on providing information on the relative importance of intraspecific differences in the mortality, growth, morphology, and attachment of *Acropora cervicornis* and *A. prolifera,* the hybrid between *A. cervicornis* and *A. palmata*.

The major questions were:

1. Are there significant differences within a coral species in mortality, growth, branching or attachment?
2. Are differences related to the origin of the coral: low-energy back reef vs. high-energy reef front?
3. Are transplantation site differences more or less important than interspecific differences?
4. Is the culture of corals on wire frames an effective method for producing second generation coral fragments for use in restoration work?

Material and Methods

For the purposes of this study, each isolated coral thicket sampled from a distinct reef was assumed to be a unique genotype, even though somatic mutation

could potentially occur within a single coral colony, causing diverse responses within samples of a particular coral. Zooxanthellae strains were also assumed identical for all replicate fragments of a specific coral, but differences between fragments could potentially arise by incorporation of new algal strains. To help control for these unlikely factors, 30 fragments were used per genotype, six replicate fragments at each of five sites.

The hybrid coral *A. prolifera* was treated as a distinct species. For each of the two species, eight thickets were selected, four from back reef areas and four from reef fronts. Morphological differences were clearly observed between the two populations of each species, and so reef front and back reef populations of each species are referred to as morphotypes. The 16 genotypes were obtained from reefs within the La Parguera reef system. Samples spanned 6 km and with two exceptions each sample reef was separated from other reefs by wide channels 10-25 m deep. Fragments were sampled from within a single, large, distinct coral colony or from a tight group of adjacent colonies (thicket) widely isolated from other corals of the species.

Frames for supporting coral fragments were constructed by bending 0.5 m x 1 m pieces of vinyl-coated 2.5 x 5 cm wire mesh into A-shaped frames, one meter long and standing about 25 cm high. Unbranched 8-12 cm apical coral fragments were attached to the frames with 10 cm plastic cable-ties, color-coded to denote replicate fragments of each genotype. Each fragment was secured at a mesh junction so that frame overgrowth could occur in all four directions along the wire. Separate frames were used for each species and for back reef and reef front corals, so there were four frames per site. All frames were located directly adjacent to one another on the sand substratum, randomly ordered and within 1-3 m of each other (split-plot design). The frames were weighted with short segments of heavy metal bars (Bowden-Kerby 2001a).

For the ANOVA analyses, mortality and relative growth means included data from all branches of each coral genotype. To minimize the hidden effects of breakage and mortality on branching, a branching density for each genotype was calculated based on half of the branches (3 out of 6), those with the highest relative growth per site. Branch density index was calculated as the length of the main branch in mm + 2 x length secondary branches + 3 x length tertiary branches ÷ total length of branches x 100. For overgrowth (attachment of the fragments to the frames), means were calculated based on the three maximum overgrowths per genotype per site, effectively eliminating branches or branch bases that had died.

For data presentation, each coral genotype was assigned a letter code: 'B' for back reef, 'F' for reef front, 'c' for *A. cervicornis*, 'p' for *A. prolifera.* Thus, Bc = back reef *A. cervicornis*, Fc = reef front *A. cervicornis*, Bp = back reef *A. prolifera*, Fp = reef front *A. prolifera*. Each genotype was also assigned a number from 1-4, with the number assigned based on the mean relative growth rates in descending order.

Results

Figure 1 shows mean mortality after one year for each coral genotype by site of origin. Comparing the genotypes in a randomized complete block design ANOVA, arcsine transformed data showed significant differences in mortality among reef front coral genotypes for both *A. cervicornis* ($p<0.0005$) and *A. prolifera* ($p<0.025$), however the ANOVA showed no significant differences in mortality among back reef genotypes of either *Acropora* species ($p<0.25$ in both cases).

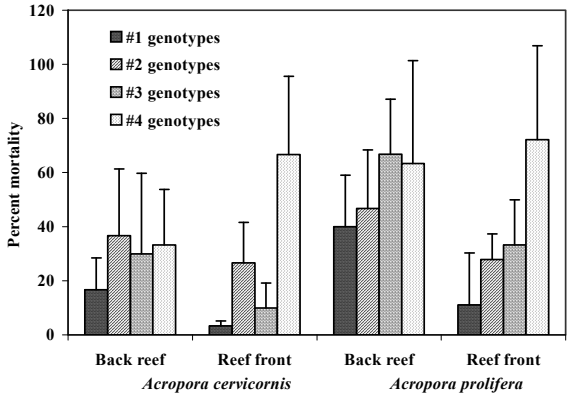

Figure 1: Mean percent mortality +SD of *Acropora* genotypes grown together for one year (n=30 per genotype, 5 sites x 6 branches; 3 sites for reef front *A. prolifera*. Genotypes are ordered based on relative growth: #1 with the highest, #4 the lowest.

Mean relative growth after one year is summarized in Figure 2. The results indicate the rapid growth of the various genotypes of each *Acropora* morphotype, ranging from a ten to twenty fold increase in branch lengths for *A. cervicornis* and from six to over thirty-fold increase over the year for *A. prolifera*. Two-way ANOVA comparisons indicate significant differences in relative growth among genotypes within coral morphotypes with transplant site as a factor (Bc: $p<0.025$, Fc: $p<0.025$, and Bp: $p<0.05$), except for genotypes of reef front *A. prolifera* (Fp: $p<0.50$). This lack of significance is likely due to smaller sample size, as only two sites included this morphotype due to a shortage of coral material.

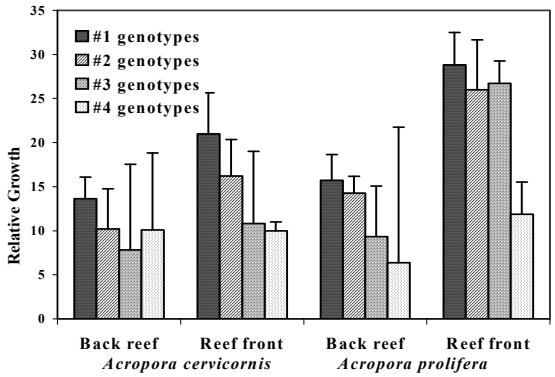

Figure 2: Mean relative growth based on maximum branch per site per coral genotype +SD (n = 4: 1 branch per coral genotype x 4 sites, 2 sites for reef front *A. prolifera*).

Figure 3 exemplifies comparisons that included all six branches per genotype per site. ANOVA comparing genotype means gives highly significant results for all but the Fp morphotype. (Bc: $p < 0.00001$, Fc: $p < 0.0001$, Bp: $p < 0.035$, Fp: $p < 0.3$). An interesting genotype-specific ordering of growth was observed for all four coral morphotypes, with particular genotypes growing fastest or slowest nearly everywhere, regardless of transplantation location (Fig. 3). This figure also shows the poor growth at the Media Luna offshore site due to extensive breakage. As breakage was considered a nuisance variable to the experimental questions, this site was excluded from the analysis. Without exception, the mortality ranking (high to low) of each genotype was the same as their relative growth ranking. This was the case when analysis included dead, broken, and lost branches, as well as when analysis was based only on the maximum branch per genotype per site.

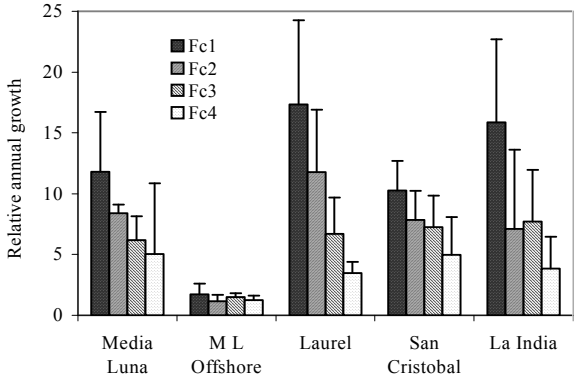

Figure 3: Site specific relative annual growth + SD of four genotypes of the reef front morphotype of *Acropora cervicornis* grown together on frames at five back reef locations. Each pattern represents a particular genotype (n = 6 branches per location).

Branch density data (Fig. 4) indicates that *Acropora prolifera* overall had a branch density index more than twice that of *A. cervicornis*. Comparisons between back reef and reef front morphotypes demonstrated no significant morphotype-specific differences in branching density within each species (paired *t*-tests: *A. cervicornis,* p=0.32; *A. prolifera*, p=0.39). Comparisons within each morphotype of the four genotypes indicated differences in branch density, confirmed to be statistically significant by randomized complete block ANOVA (Bc: $p<0.003$, Fc $p<0.005$, Bp: $p<0.025$, Fp: $p<0.05$). However, site was sometimes more significant than genotype in influencing branching (Bc: $p<0.005$, Fc $p<0.0005$, Bp: $p<0.0025$, Fp: $p<0.12$).

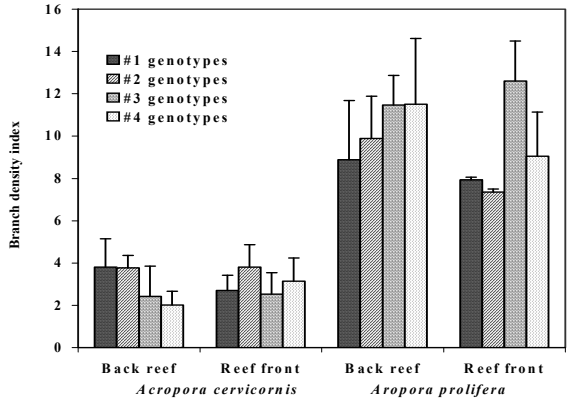

Figure 4: Mean relative branching +SD of *Acropora* genotypes grown together for one year in the back reef (n = 12: 3 branches x 4 sites; 2 sites for reef front *A. prolifera*).

Figure 5 shows mean overgrowth for each genotype of the four *Acropora* morphotypes, indicating a genetic basis for faster overgrowth of reef front corals, plus a generally positive relationship between relative growth and overgrowth. Randomized complete block design ANOVA of the data at one year gives statistically significant differences between genotypes for all morphotypes except for back reef *A. cervicornis* (Fa: $p<0.013$, Bp: $p<0.03$, Fp: $p<0.05$) (Bc: $p<0.38$.)

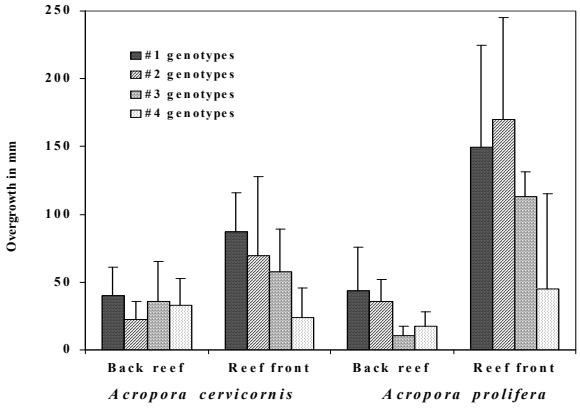

Figure 5: Mean overgrowth of *Acropora* genotypes in mm +SD onto wire mesh frames at one year (n= 15: 3 branches per genotype x 5 sites, 3 sites for reef front *A. prolifera*).

The experiment started with 10-cm fragments with little difference in thickness between apical fragments from the back reef and reef front. However, *A. cervicornis* from the reef front developed a distinctly more robust morphology than the back reef morphotype in the calm growth conditions of the back reef over the year. Statistically significant differences between the mean diameters of the two *A. cervicornis* morphotypes from the apical ($p=0.002$), middle ($p<0.00005$), and basal ($p<0.000005$) colony regions were revealed (Fig. 6) with *t*-tests. In addition to branch thickness, branch tips of the reef front morphotype were also noticeably softer and easily crushed, indicating a more porous, less heavily calcified skeleton than the lagoonal morphotype. Color differences were often apparent between the two morphotypes as well, the back reef type being more uniformly golden brown, while the robust reef front morph often had a darker brown or gray to purplish hue.

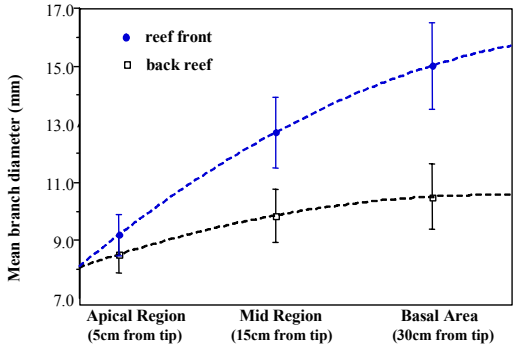

Figure 6: Comparison between reef front and back reef morphotypes of *Acropora cervicornis* grown together for one year, showing mean branch diameters ± SD for three colony regions.

Discussion

Based on this study, coral genotype appears to be more important than transplantation location, with 75% of all tests being significant for genotypic effects, as compared to only 44% of experimental outcomes having significant location effects. A G-test comparison of the observed frequencies confirms this ($p<0.005$, $G=8.3$, 1d.f.). However, genotype and location were equally as important for back reef morphotypes transplanted to the back reef, but for reef front morphotypes genotype was significantly more important than site in predicting experimental outcomes ($p<0.00001$, $G= 36.7$, 1d.f.). A potential explanation for the greater number of statistically significant differences among reef front corals transplanted to the back reef is that only certain genotypes from the reef front can adapt well to back reef environments, while genotypes from the back reef are in general well-adapted to the environment and therefore more even in their responses.

These results confirm that there is a biological basis for obtaining transplants from areas as similar as possible to the planned restoration site. *A. cervicornis* appears to be a highly diverse generalist species, not because each genotype has a high environmental tolerance, but because the species is composed of a diversity of genotypes, each adapted to a specific range of tolerances. Sourcing corals from environments similar to a restoration site and incorporating a high level of genetic diversity into transplantation projects would help ensure successful results for at least some of the transplants.

Based on genotypic differences alone, mean relative growth rates within *A. cervicornis* morphotypes growing together in the back reef varied by more than a factor of three, while mean relative growth rates within *A. prolifera* varied by a factor of six. These findings are in agreement with earlier studies which suggested that coral genotype strongly affected the ability of individual corals to thrive in a particular environment (Potts 1984; Edmunds 1994; Takabayashi and Hoegh-Guldberg 1995; Hoegh-Guldberg et al. 1997). A next step in advancing future research on the issue of environmental adaptation of coral genotypes might involve taking replicate fragments of specific genotypes and transplanting them into highly variable conditions of water flow, depth/light, and temperature.

A possible cause for the significantly slower growth and higher mortality of the reef front *A. cervicornis* genotype Fc4 could be that this genotype contains a maladapted zooxanthellae strain, perhaps even the zooxanthellae species identified by Baker et al. (1997), adapted to light conditions at greater than 9-12 m deep.

A possible non-genetic or non-zooxanthellae driven basis for differences in coral growth among genotypes could be the presence or absence of sublethal levels of pathogens within a corals sourced from the same thicket. In this study, there was an indication that disease may have suppressed the growth of genotype Fc4, which had significantly higher mortality ($p<0.0005$) than other genotypes. Of the 30 replicate Fc4 fragments, 66.7% died during the year, and much of this was visibly due to disease. This contrasts strikingly with the fastest growing genotype of this morphotype (Fc1), with only 3.3% mortality. Colonies of Fc4 appeared to be healthy during the first six months of the study, although displaying a noticeably slower growth rate. “White band” disease was later observed killing this genotype at several locations, while very few corals of the other genotypes had the disease. It appears that genotype Fc4 is either more susceptible to this disease, and the disease organisms were widespread throughout the reef system, or perhaps the disease was present in the

tissues of the source colony. The slower growth could have been the outcome of fighting a disease over several months, until the fragments eventually succumbed.

Bottjer (1980) studied the morphology of *A. cervicornis* from both reef front and back reef populations and surmised that the distinctly stockier morphology of the fore reef corals was environmentally induced. However this study suggests a genetic basis to this morphology. The reef front morphotype also had 14.6% less partially dead area in the lower portions of colonies than the back reef type (p=0.005, paired *t*-test), indicating that this morphotype of *A. cervicornis* invests more energy in maintaining healthy tissues in lower colony portions. The greater ability of reef front genotypes to attach themselves firmly to the substratum appears to be a genetically determined adaptation for survival and persistence in rocky reef front conditions, enabling coral fragments to attain a rapid and strong foothold. Baker et al. (1997) suggest the possibility of a cryptic species occurring within *A. cervicornis*, based on the occurrence of two distinctly different zooxanthellae taxa that were never found to co-occur in an individual coral. While the cryptic species proposed by them were segregated by depth, the *A. cervicornis* morphotypes of this study are segregated according to energy regime.

This study showed that morphological variation between back reef and reef front populations of *A. cervicornis* was relatively fixed. On the other hand, *A. prolifera* from the reef front changed growth form completely when grown in the back reef, transforming to become indistinguishable from the back reef genotypes. The thick-branched, open form described in Vaughan (1901), transformed into that of the undescribed slender-branched, bushy back reef type, indicating a plastic morphology based primarily on environmental influence. The back reef and reef front growth forms of *A. prolifera* thus conform to the definition of "ecomorphs", while the two forms of *A. cervicornis*, being independent of environmental causation are more accurately referred to as morphotypes.

If environmental conditions in the Caribbean have become unfavorable to the long-term survival of *A. cervicornis* as a species, coral transplantation might be used as part of a mitigation and recovery strategy. Artificially increasing the genetic diversity within monoclonal populations would potentially enhance natural fertilization rates, increasing sexual recruitment and genetic recombination and thus accelerating the recovery and adaptive potential of this ecologically important coral species. Another measure might include rescuing genetic material from declining *A. cervicornis* populations, transplanting and culturing coral fragments on frames as described in this study, as long as these transplantation efforts did not cause additional mortality. Reestablishing a more natural balance of herbivores on reefs where other factors such as siltation are not overpowering would potentially both increase the recruitment of coral larvae and the survival of remaining *A. cervicornis* populations. Effective interventions based on transplantation to conserve and restore *A. cervicornis* and *A. prolifera* will require further clarification of the population genetics of these species. Of course any recovery strategy will prove futile if the factors leading to coral reef decline in the Caribbean region are not reversed.

Abstract. Detached *Acropora palmata* fragments (n=1857) generated by the *M/V Fortuna Reefer* grounding off Mona Island, Puerto Rico were secured to reef substrates or dead standing *A. palmata* skeletons using stainless steel wire. After 10 years, only 6% (n=104) of the fragments were alive, of which half (n=54) exhibited extensive branching (mean = 5 branches, 89 cm length), and a substantial increase in height (mean = 39 cm). Most surviving fragments were 20-100 cm (original length when first restored), secured to the reef and oriented upright. Fragments died or were lost in the first three years from wire breakage (23%), overgrowth by bioeroding clionid sponges (16%) and other factors (5%). Over the next 7 years, another 50% died due to gastropod predation, additional wire breakage and detachment during storms, and continued overgrowth by *Cliona*. Fragments attached to *A. palmata* skeletons initially grew rapidly and produced new branches, but most were subsequently dislodged due to bioerosion and breakage of the skeleton to which they were attached. Low fragment survival is attributed to 1) wire failure and inability of corals to overgrow wire, 2) limited fragment fusion, 3) attachment of fragments to inappropriate substrates, and 4) progressive mortality of large, older basal portions of detached colonies that failed to grow. Natural stressors unrelated to the restoration including diseases, predators, and bioeroding sponges have increased over time within and outside the grounding site and are also impacting fragment survival. Restoration may be a viable means to promote recovery of acroporid populations if the use of uncoated wire to attach fragments is avoided; fragments are placed on suitable substrates with live tissue in direct contact with the substrate to promote fusion, and efforts to mitigate disease and corallivory are undertaken.

Key words: *Acropora palmata*, Elkhorn coral, Restoration, Ship grounding, Coral disease.

Introduction

Since the listing of *Acropora palmata* on the U.S. Endangered Species Act in 2006, interest in recovering degraded and damaged populations of this species through restoration is increasing. Historically, most restoration efforts in the U.S. were conducted in response to ship groundings. Small scale restoration projects for *A. palmata* are now also being implemented after hurricanes and other catastrophic disturbances to minimize tumbling, scouring and loss of fragments associated with high wave energy and sand and rubble movement. Cement, epoxy, metal wire, cable ties, and/or molly bolts have all been used to reattach *A. palmata* fragments, with varying degrees of success (Precht 2006). Fragments have also been secured to artificial (cement) and natural (limestone rocks) structures, including reef crowns, rosettes, and limestone boulders, with further stabilization using molly bolts or other anchoring systems (Bruckner 2003). Fragments at the Fortuna Reefer site were attached to dead standing *A. palmata* skeletons to raise them off the substrate and to promote resheeting over dead skeletons (NOAA 1997; Iliff et al. 1999; Bruckner and Bruckner 2001).

The first major restoration effort for *A. palmata* in Puerto Rico was undertaken following the *M/V Fortuna Reefer* grounding on July 24, 1997. The grounding and removal of the vessel damaged shallow reef habitat dominated by *A. palmata* and *Diploria strigosa*. The reef substrate was crushed and fractured along the inbound and outbound tracks of the vessel, extending from the reef crest approximately 300 m seaward (2-4 m depth) and up to 30 m in width, with collateral damage to surrounding areas from cables used to extract the vessel (NOAA 1997).

An emergency restoration was completed within three months of the incident. The restoration focused on the reattachment of broken and dislodged *A. palmata* colonies and branches throughout the site of impact using stainless steel wire. Because of reports of frequent wire breakage and fragment loss, a mid-course correction using a stronger wire was undertaken in 2000 to prevent further fragment loss

(Bruckner and Bruckner 2001). This paper describes the fates of the fragments over 10 years, including patterns of survival, regrowth, and sources of mortality. The restoration techniques used at this site are evaluated and recommendations are presented on alternative approaches that may enhance the success of future restoration efforts for this species. Natural causes of mortality, unrelated to the grounding, are also discussed, along with options to mitigate these.

Material and Methods

Between September and October 1997, restoration experts stabilized detached *A. palmata* colonies and branches (n=1857) throughout the grounding site (2-6 m depth) off the southeast coast of Mona Island (18°02'N; 67°51'W; Fig. 1). Coral fragments (15-340 cm in length) were secured to the reef by wrapping stainless steel wire over coral fragments and around stainless steel nails that were inserted into pre-drilled pilot holes. Additional fragments were attached to dead standing *A. palmata* skeletons using wire and/or cable ties (NOAA 1997).

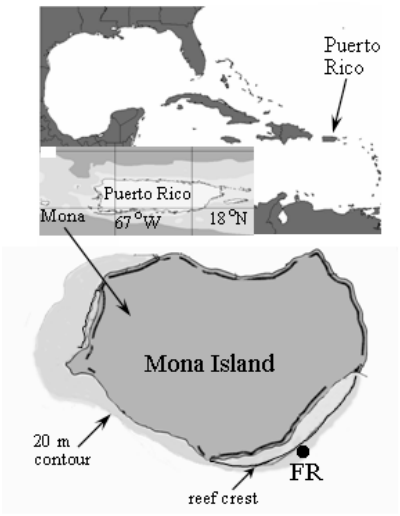

Figure 1: Location of the Fortuna Reefer (FR) restoration site.

We first examined the site in February 1998, and subsequently monitored changes to fragments and unmanipulated colonies and fragments in surrounding areas 1-3 times per year through February 2008. The initial survey involved an assessment of the number, size, and condition of fragments that remained attached, and the number of fragments that were detached and displaced or missing. Detached and missing fragments were identified from 1) groupings of nails within the reef without attached fragments; 2) remnant wire on skeletons that was not associated with fragments; and 3) unsecured fragments with remnants of attached wire that accumulated in sand channels or were scattered throughout adjacent fore and back reef habitats.

For each remaining fragment, measurements of the size (maximum length to nearest cm), orientation (up, down or sideways with respect to their orientation prior to breakage), origin (branch end, middle, or base of colony), location of attachment (reef or skeleton), and condition (live or dead) were recorded. Live fragments were also evaluated for tissue growth over the wire, presence and size of proto-branches, natural cementation (fusion) to the substrate, and resheeting over *A. palmata* skeleton. Estimates of size (length, width, height), percent remaining tissue, and old vs. recent mortality were made from a planar perspective using a 1 m bar (marked in 1 cm increments) oriented along the long axis of the fragment. Partial mortality was recorded as the percent loss from the upper surface of the reattached branches, and does not include the undersides of branches. All fragments were presumed to have 100% of their upper surface covered with tissue when first reattached in 1997.

Causes of partial or total mortality were identified as disease [white band disease (WBD), Caribbean ciliate infections, white patch (pox) disease, or growth anomalies], overgrowth by boring sponges (*Cliona* spp.), predation by snails (*Coralliophila abbreviata)*, polychaete worms (*Hermodice carunculata),* parrotfish *(Sparisoma viride*), macroalgal competition, or three-spot damselfish *(Stegastes planifrons*) territories. If the cause of mortality could not be determined, it was recorded as unknown.

Results

A total of 1857 fragments were reattached in 1997. Most surviving fragments (n=104; 5.6%) identified in February 2008 were attached to the reef (n=78; 75%) or dead *A. palmata* skeletons (n=26; 25%) and oriented upright (92%). A number of additional fragments that were originally attached to dead skeletons (n=28) had become detached due to wire failure and breakage of the underlying branches, and had accumulated in sand channels (Fig. 2). Over half (63%) of the surviving fragments had living tissue on most of their upper branch surfaces (>80%) and numerous branches (3-23 branches, 15-70 cm length); these had increased in height (20-80 cm) and width (15-150 cm). Other surviving fragments (37%, n=38) consisted of large (>80 cm length) middle and basal portions of broken colonies. These exhibited minimal signs of new growth over 10 years and a lack of fusion as the fragments were progressively losing tissue (mean=37% live tissue). Few fragments firmly fused to the reef substrate or coral skeletons (12%), and none of the fragments attached to dead skeletons successfully grew tissue over the underlying skeletal surfaces to which they were attached.

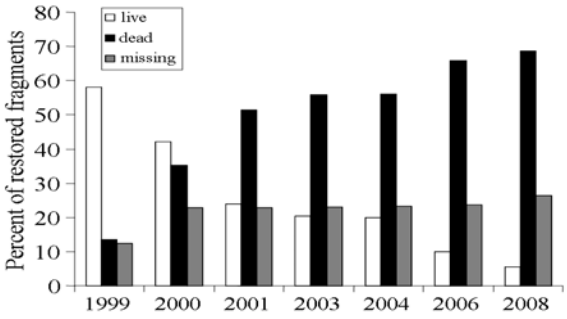

Figure 2: Changes over 10 years in the proportion of restored fragments (total=1857) that were still alive (white bars), dead (black bars) and detached and/or missing (grey bars).

Original fragment length, orientation (up or down), position on the source colony (e.g., branch end or middle) attachment location, and depth were important factors in the long-term survival of restored fragments (Fig. 3). The highest survival was recorded from 1.5-4 m depth, especially medium sized fragments (20-100 cm length) that were oriented upright and were attached to reef substrates. Small and medium-sized fragments attached to dead skeletons initially exhibited high rates of growth, but most were directed upward by production of new branches with only limited resheeting onto the dead coral substrates.

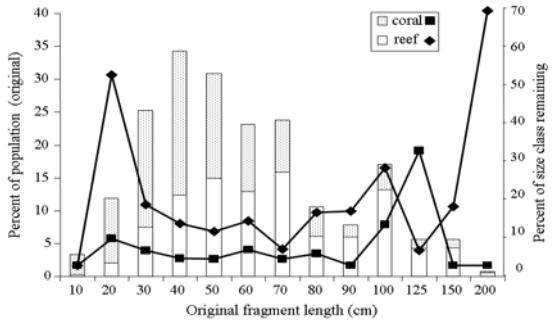

Figure 3: Percent of live fragments in each size class when initially restored (stacked bars) divided into fragments attached to the reef (white bars) and dead skeletons (grey bars), and the percent within each size class that was still alive after 10 years (line graph), attached to the reef (diamond) or to dead *A. palmata* skeleton (square).

Wire failure resulted in the loss of 23% (n=427) of the restored fragments in the first three years (prior to the mid-course correction). An additional 7% (n=55) of the fragments that were rewired in 2000 were lost during years 8-10, primarily due to breakage of underlying *A. palmata* skeletons as the fragments increased in size and branching complexity. Overgrowth by the boring sponge (*Cliona* spp.) was responsible for 22% total loss with 5% of the survivors currently affected by *Cliona* (Fig. 4). Mortality from *Cliona* was attributed to placement of fragments on or near substrates colonized by this sponge. Coral diseases identified throughout the site included WBD (7.3% of all fragments affected over 10 years), ciliate infections (3.2%), white patch disease (0.3%), and growth anomalies (1.3%). Numerous fragments died from WBD (5.8%), and the prevalence of WBD steadily increased from 2003-2008 (Fig. 4), while other diseases caused minimal partial mortality. Corallivorous gastropods (*C. abbreviata*) increased in abundance (maximum = 286 snails/survey) and density over time, affecting 17% (n=315) of all fragments over 10 years. These gastropods were found on fragments and colonies with WBD, as well as healthy corals, but they formed larger aggregations on stressed corals (6-40 snails per coral vs. 1-5 on "healthy" fragments), especially fragments that were dislodged and deposited in the sand. Damselfish algal lawns (1.1%), parrotfish predation (0.1%), and algal overgrowth (0.2%) were rare. The site was invaded by a crustose coralline algae (*Peyssonnelia* spp.) in 2006, which is rapidly spreading and has recently begun overgrowing corals. No bleaching was observed among *A. palmata* colonies or fragments during the 1998 and 2005 mass bleaching events or other years.

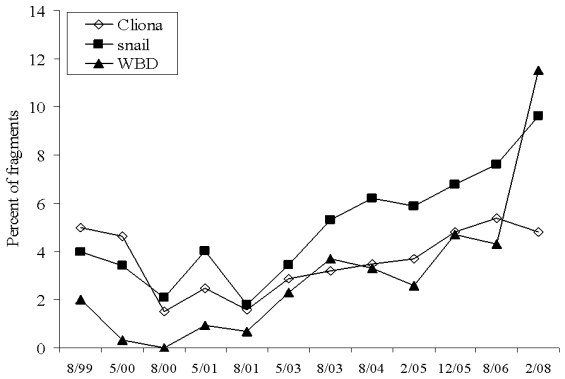

Figure 4: Major causes of partial and whole fragment mortality. A total of 22% of all fragments were overgrown by *Cliona* spp. (open diamonds), 5.8% were killed by WBD (triangles), and 17% were preyed on by *C. abbreviata* gastropods (square).

Discussion

Ten years after completion of the *M/V Fortuna Reefer* restoration, only about 6% of the fragments remain alive. About half of these have continued to grow and have produced numerous branches, recreating the structural complexity of an *A. palmata* reef. Other survivors, primarily the largest basal and middle portions of the colonies, failed to produce protobranches and are continuing to lose living tissue. A significant proportion of the fragments died from natural stressors unlikely to have resulted from the grounding or restoration. This includes pervasive and increasing predation pressure by *C. abbreviata* and an

outbreak of WBD that began five years after the grounding. Substantial loss in the first 2 years and over the longer term was also directly related to the restoration techniques used to secure the fragments, substrates selected for attachment, orientation of fragments, and attachment of larger, older basal parts of the colony with a lower likelihood of survival.

Attachment methods

"Traditional" methods to reattach coral fragments, including cement, epoxy, and cable ties were first attempted at the *M/V Fortuna Reefer* site. Cement offered the most efficient, natural, and cost-effective approach to secure fragments, but it was difficult to use due to the long setting time required and the heavy surge at the time of the restoration. A quick setting 2-part epoxy was also impractical because it was neutrally buoyant and larger fragments failed to properly adhere to substrates if algae, sediment, and sessile invertebrates were not thoroughly removed. Fragments secured initially to *A. palmata* skeletons with plastic cable ties were reported to loosen under surge conditions; thus, stainless steel wire was used (NOAA 1997; Iliff et al. 1999).

Over 10 years, wire proved to have numerous drawbacks. Considerable time was spent inserting stainless steel nails into reef substrates to provide a holdfast for the wire. This necessitated use of a hydraulic drill and a compressor to drill holes and cement to secure the nails. Another limitation of wire was the difficulty in securely attaching fragments to the reef to dampen wave surge effects. The slight, continuous movement of the fragments hampered their ability to fuse naturally and wire abraded the coral tissue, resulting in extensive partial fragment mortality (Bruckner and Bruckner 2001). Stainless steel wire used at the site also became pitted and broke, necessitating a mid-course correction after three years. Fragments were rewired using a stronger Monel nickel/copper alloy wire, but this also began to break after 4-5 years contributing to further fragment loss. Both types of wire also provided a substrate for accumulation of macroalgae and attachment of *Millepora alcicornis*, further compromising fragment health (Bruckner and Bruckner 2006b).

Cable ties are the optimal choice for reattachment of *A. palmata* on shallow exposed reefs, as coral tissue and skeleton is rapidly accreted over the plastic, and cable ties can be firmly tightened, although multiple ties may be required to prevent loosening. As a pilot experiment, we secured fragments removed from colonies with WBD to *A. palmata* skeletons using cable ties (n=23) and underwater two part epoxy. After four years only a single branch attached with cable ties was detached while all fragments attached with epoxy were lost; all other fragments secured with cable ties (94%) fused to the skeletons and overgrew the plastic (Bruckner and Borneman unpub. data). During the mid-course correction, a small number of fragments in shallow water were reattached to the reef substrate with cement. While several of these have died, none have become detached. Over the long-term, cement or some of the newer, commercial underwater epoxies like Allfix and Z-Spar may prove to be the most successful, cost-effective, and rapid method to reattach fragments, especially if the fragments are temporarily secured with plastic-coated wire or cable ties to allow time for cement to set. Plastic coated wire is likely to facilitate tissue overgrowth and reduce the likelihood of wire breakage but still must be monitored frequently to avoid loss of fragments due to storms.

Substrates for attachment

Fragments were attached to branches of dead standing *A. palmata* colonies with the expectation that they would attach to the dead branches and resheet over the skeleton, thereby restoring the three dimensional topographic relief much more rapidly (NOAA 1997; Iliff et al. 1999). Few fragments accreted tissue and skeletal material onto adjacent branches, and none grew back down the colony. Instead, most growth was directed upward in the form of new branches. These continued to increase in size and weight, creating more wave resistance until the underlying skeleton broke. The fragments were subsequently dispersed, overturned and deposited in sand flats, or removed from the site. Placement of fragments above the substrate had minimal benefits at reducing disease prevalence or corallivore abundance; and overgrowth by *Cliona* was actually higher than that observed in fragments attached to the reef (Bruckner and Bruckner 2006a), possibly because *Cliona* colonizes dead corals more frequently than the reef substrate. Fragments secured in an upright position to the base of colonies may have a better chance of fusion and resheeting as they grow upward.

Branch size and origin

Restored fragments ranged in length from 15-340 cm and included branch ends, as well as older colony bases and middle. Branch ends up to ~100 cm exhibited the highest rates of survival and growth, and greatest ability for natural fusion. Many of the largest basal and middle portions survived over 10 years, but they were affected to a greater degree by disease and corallivory, and very few developed new branches. In fact, most failed to grow at all, and instead slowly lost living tissue over 10 years. These fragments also often lacked tissue on their undersides when first restored, reducing their ability to fuse. Due to their large size, stabilizations and attachment is more labor

intensive, while small to medium sized branch ends can be relocated and secured more rapidly with cable ties, cement, or epoxy. Larger fragments could be positioned (but not attached) onto hard substrates to reduce scouring and smothering by sediment, and their weight and structural complexity alone may be sufficient to minimize movement. The time required to secure these could be better invested into attaching a greater number of smaller branch ends.

Enhancing natural fusion

Only a limited number of fragments, primarily smaller branch ends with live tissue on the upper surfaces and undersides when first attached, accreted tissue and skeleton onto the underlying substrate over 10 years. Other branches were unable to reattach, mainly because the branches were not positioned such that living tissue was directly in contact with the substrate, and fragments exhibited slight back and forth movement during wave surge. Fusion may be enhanced by placing fragments at a slight angle such that a portion of the living surface of the branch was in contact with exposed, algal-free substrate. Ensuring contact of living tissue with a hard substrate free of algae may provide adequate time for natural fusion, thereby minimizing losses at a later stage when the wire breaks.

Controlling natural stressors

The gastropod *Coralliophila abbreviata* is a significant predator of *A. palmata* and may also be a vector for disease (Bruckner et al. 1997; Williams and Miller 2005). If snails occur within the restoration site, these should be removed while the restoration is underway, with additional removal as needed during annual monitoring to minimize tissue loss. Collection of *C. abbreviata* into sealable plastic bags for disposal on land is recommended due to their brooding life history strategy. We conducted a snail removal experiment from this site in Aug 2006. After 1.5 years, a large number of snails recolonized the area, but far fewer than before (Bruckner and Borneman unpubl. data). Although the causative agent of WBD remains elusive, and few attempts to treat WBD-affected corals have been undertaken, branch ends removed from colonies with WBD and attached to surrounding substrates exhibited high rates of survival, while the source colonies completely died (Bruckner and Borneman unpubl. data). One other stressor, the bioeroding sponge *Cliona*, readily overgrew fragments placed on or next to it. *Cliona* also spread to new areas, increasing in cover over the duration of this study. Placement of fragments away from competitive species (such as, *Cliona* and *Palythoa*), minimizes the likelihood of overgrowth, and may allow ample time for fusion and growth of fragments.

Success of future restoration efforts directed at this species may be enhanced by taking into consideration the environmental conditions affecting the site and suitability of the site for restoration including physical factors such as wave exposure, condition of reef substrates (e.g., cover of macroalgae and bioeroding sponges), and presence of disease and corallivores. Specific restoration techniques including the use of materials that do not negatively affect living tissue, placement of fragments on suitable (cleaned) substrates, orienting fragments such that live tissue contacts the substrate, and selection of small to medium sized branch ends can enhance survival and possibly speed up ecological recovery of the site.

Abstract. The effectiveness of macroalgal reduction and *Diadema antillarum* addition in limiting macroalgal growth and facilitating coral recovery was investigated between June 2002 and July 2003. Two treatments, one involving the manual reduction of macroalgae, and another involving macroalgal reduction followed by the addition of *D. antillarum*, were each performed on a set of three replicate patch reefs off the island of Eleuthera, The Bahamas. Mean macroalgal cover was reduced to <2% immediately after macroalgal reduction, but neither treatment was effective at preventing macroalgal re-growth after 12 months. Mean juvenile coral density increased by more than 150% immediately after macroalgal reduction. No significant change in mean coral cover was detected for either treatment or the control between 0 mo and 12 mo and an increase in mean juvenile coral density observed on some reefs during this period cannot be attributed to the effectiveness of either treatment. The failure of the treatments in significantly limiting macroalgal growth and facilitating coral recovery was likely due to poor *D. antillarum* survivorship. The results suggest that the effectiveness of reef restoration efforts involving translocated or lab-reared *D. antillarum* may be limited on some reefs and may require multiple re-stocking efforts.

Keywords: Reef restoration, Macroalgal removal, *Diadema antillarum*, Bahamas, Patch reefs

Introduction

The vitality of coral reefs worldwide continues to decline despite heightened concern and the substantial efforts committed by hundreds of government agencies and nongovernmental organizations (Birkeland 2004). It may be necessary to supplement efforts to address climate change, overharvesting, coastal eutrophication, sedimentation and other threats with direct intervention at a local scale to help spur reef recovery in areas where these threats have been minimized, but where reef recovery has not been evident. The aim of this investigation was to assess the combined effectiveness of macroalgal reduction and the addition of *Diadema antillarum* Philippi on patch reef communities in the Bahamas. Macroalgal reduction, combined with the enhancement of *D. antillarum* population densities, may help facilitate localized phase-shift reversal on Caribbean/Western Atlantic coral reefs.

Materials and Methods

This study was conducted between June 2002 and July 2003 on a series of small patch reefs (4.9-8.3 m^2) found in 10 to 11 m of water off the northwestern coast of Cape Eleuthera, Eleuthera, The Bahamas. Nine experimental reefs were selected at random from a set of 20 patch reefs. Separate sets (= three replicates) of reefs received one of two treatments: macroalgal reduction (Treatment A) or macroalgal reduction combined with the addition of *D. antillarum* individuals (Treatment B). A third set of reefs did not receive any treatment and served as the control. Macroalgae were removed from the experimental reefs by hand. *Diadema antillarum* were collected from a nearby fringing reef and translocated to Treatment B reefs. The urchins were individually placed on the reefs with a target population density of approximately 4 m^{-2}. All Treatment B reefs were re-stocked with urchins at t = 5 mo, as no urchins survived from the initial translocation.

Surveys designed to monitor changes in coral and macroalgal cover, algae biomass, juvenile coral density, and coral health were conducted on the experimental reefs during the course of the 12-month investigation. Macroalgal and coral percent cover was quantified by filming non-overlapping transects placed across the length of each reef with a digital video camera at t = 0 (pre-treatment), t = 0^{post} (immediately post-treatment), t = 5, and t = 12 mo. The number (2-3) and length (2-4 m) of the transects varied depending on the size of reef. Percent cover estimates were obtained by analyzing consecutive, non-overlapping video frames using PointCount99®. Twenty-five randomly-generated points were used for

each frame; a minimum of thirty frames were analyzed for each reef. The percent cover value for each video frame was considered a sample; all samples from a single reef were pooled to obtain mean macroalgal and coral cover values for each reef. For comparison between treatments, mean macroalgae and coral cover values for each treatment were obtained by pooling all samples from all replicate reefs.

Algae were collected from four random sample quadrats (0.0625 m^2) for each reef at t = 0 and t = 12 mo. All macroalgae and most turf algae were removed from each quadrat and placed into individual sample bags. The samples were rinsed and separated into algal groups: fleshy green, fleshy brown, and calcareous green. The samples were dried and then weighed using an Acculab v1-200 balance (200g capacity, 0.01 g readability). The mean algae dry-weight value for each reef was obtained by averaging the algae dry-weight values for all samples taken from each reef. Mean algae dry-weight values for each treatment were obtained by pooling all samples for all reefs that received the same treatment.

Attempts to conduct a visual census of all juvenile corals on Treatment A and Treatment B reefs were made at t = 0 mo, t = 0^{post} mo, and at t = 12 mo, while the control reefs were surveyed only at t = 0 mo and at t = 12 mo. Juvenile corals were located by closely inspecting the substratum; they were identified to species when possible. Measurements (mm) were taken at the longest axis of the polyp or colony. Only corals with 20 polyps or fewer and a diameter $\leq$ 4cm were counted. Mean juvenile coral count values for treatments were obtained by averaging the total counts for reefs receiving the same treatment at each sampling period. The total number of juvenile coral individuals was normalized by reef area and reported as density (colonies m^{-2}). A visual census for adult and juvenile *D. antillarum* was conducted in conjunction with the juvenile coral survey.

Three 0.0625 m^2 permanent quadrats were established on each reef prior to treatment and filmed at t = 0 mo, t = 0^{post} mo, t = 5 mo, and at t = 12 mo, to examine fine-scale changes in the benthic community, focusing particularly on coral/algal interactions and sources of coral mortality and tissue stress.

An equal variance *t*-test was used to compare pooled treatment data between various time intervals. The equivalent non-parametric test (Mann-Whitney *U* test) was used when data did not satisfy the assumptions of normality and homoscedasticity or if the sample size was very small (n < 5). A one-way ANOVA or the equivalent non-parametric test (Kruskal-Wallis one-way ANOVA on ranks) was used to compare treatments and reefs at each time period; Tukey-Kramer Multiple Comparison test or the equivalent non-parametric test (Kruskal-Wallis Multiple-Comparison Z-value Test) was used to determine the sources of significance.

Results

Macroalgal reduction lowered mean macroalgal cover to approximately 2% on both Treatment A and Treatment B reefs between t = 0 and t = 0^{post} mo (Mann-Whitney *U*, $p < 0.001$)(Fig. 1A). Treatment A reefs and the control reefs exhibited increases in mean macroalgal cover of 31.4% and 19.3%, respectively, between t = 0 and t = 12 mo (Mann-Whitney *U*, $p < 0.001$; equal variance *t*-test, $p < 0.001$). No change in mean macroalgal cover was detected on Treatment B reefs between t = 0 and t = 12 mo. Mean scleractinian coral cover on Treatment A and Treatment B reefs appeared to increase by 66.7% and 50% respectively, immediately following treatment, but these change were not significant (Mann-Whitney *U*, $p = 0.078$ and 0.091, respectively). No significant changes in mean scleractinian coral cover were observed for either treatment or the control between any other sampling periods (Fig. 1B).

In contrast to the decrease in algae biomass expected for Treatment A and Treatment B reefs, both treatments and the control exhibited a significant increase in mean algae dry weight after 12 mo (Fig. 1C). Mean dry weight values on Treatment B reefs had increased the most (72.3%), while increases of 41.6% and 60.4% were observed on Treatment A and the control reefs, respectively (Mann-Whitney *U*, $p = 0.001$, 0.002, and 0.009, respectively). Fleshy, green macroalgae dominated the algae biomass samples, with a mean percent composition across all samples of 93.1 ± 9.4%. Visual estimates suggest that *Microdictyon marinum* comprised the majority of the dry-weight for all the samples.

Mean juvenile coral density increased 286% on Treatment B reefs immediately after treatment (Mann-Whitney *U*, $p = 0.05$) (Fig. 1D). Treatment A reefs exhibited a 165% increase in mean juvenile coral density during this period, but the change was not significant at the 0.05 level (Mann-Whitney *U*, $p = 0.092$). Mean juvenile coral density on Treatment A reefs decreased 49.3% between t = 0^{post} and t = 12 mo (Mann-Whitney *U*, $p = 0.05$). Mean juvenile coral density on Treatment B reefs appeared to decrease by 55% during this period, but the change was not significant (Mann-Whitney *U*, $p = 0.1$) Mean juvenile coral density had increased by 95.7% on Treatment B reefs between t = 0 and t = 12 mo (Mann-Whitney *U*, $p = 0.038$). An apparent increase of 174% was observed on the control reefs during this period, but the change was not significant (Mann-Whitney *U*, $p = 0.1$). No significant increase was

seen on Treatment A reefs between t = 0 and t = 12 mo (Mann-Whitney *U*, p = 0.329).

No adult urchins were found on any of the experimental reefs at t = 0, t = 5, and t = 12 mo. No juvenile *D. antillarum* were found on any of the reefs prior to treatment; one juvenile was found on one reef undergoing Treatment A, immediately after macroalgal removal. Three juveniles, one on each of two reefs undergoing Treatment B and one reef undergoing Treatment A, were found at t = 5 mo, while none were found on any reefs at t = 12 mo.

Examination of the permanent quadrat video frames revealed evidence of the partial and full mortality of several coral colonies. Partial mortality and tissue discoloration as a result of macroalgal overgrowth or abrasion was evident on several colonies. White Plague appeared responsible for the full mortality of a colony of *Dichocoenia stokesii* on a Treatment A reef, and Red Band Type II was likely responsible for the partial mortality of a *Montastrea faveolata* colony on another Treatment A reef. Infestation by the boring sponge, *Cliona* sp., was also evident on several colonies.

Discussion

Mean macroalgal cover decreased markedly on both Treatment A and Treatment B reefs immediately after macroalgal reduction, but the low macroalgal cover and biomass did not persist on either set of reefs. Even though Treatment B appeared to be more effective than Treatment A in limiting an increase in macroalgal cover, Treatment B was not able to prohibit the re-growth of macroalgae. Even more striking than the increase in mean macroalgal cover exhibited by Treatments A and the control reefs between t = 0 mo and t = 12 mo was the increase in mean algae biomass exhibited by all treatments during this same time interval. This increase suggests that the treatments were ineffective at reducing algal biomass and even at preventing algal biomass from increasing during this period. The observation that algae biomass samples were dominated by fleshy green algae, and, in particular, by *Microdictyon marinum*, is in concordance with reports of extensive *M. marinum* blooms on several Bahamian islands (Woodley et al. 2000; Kramer et al. 2003; Peckol et al. 2003). Coral tissue stress and mortality caused by *M. marinum* has been observed elsewhere in the Bahamas (Dustan 1987; Kramer et al. 2003; Peckol et al. 2003). The likely increase in mean scleractinian coral cover on Treatment A and Treatment B reefs between t = 0 and t = 0^{post} can be attributed to the detection of live coral that had been hidden beneath the thick macroalgal canopy prior to macroalgal reduction.

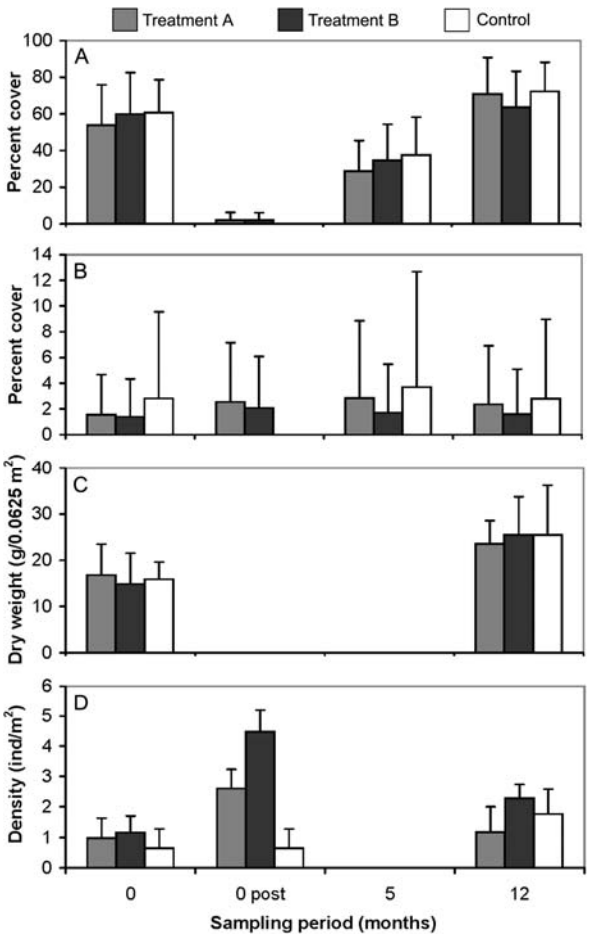

Figure 1: Mean macroalgal cover (A), mean scleractinian coral cover (B), mean algae dry weight (C), and mean juvenile coral density (D) at each sampling period. Algae dry weight data was not collected at t = 0^{post} and t = 5 mo; juvenile coral surveys were not conducted at t = 5 mo. Error bars represent + SD.

The significant increase in mean juvenile coral density on Treatment B reefs, and the likely increase observed on Treatment A reefs immediately after treatment indicates that the thick macroalgal canopy covered a substantial number (approximately two-thirds) of juvenile recruits. The presence of such a large number of juvenile corals beneath the algal canopy strengthens the case for macroalgal reduction, which would increase their access to sunlight and food – if only temporarily. Some corals evidently recruited successfully despite high macroalgal cover, but their growth and survival was likely limited (Miller and Hay 1996; Edmunds and Carpenter 2001). The absence of any significant increase in juvenile coral density on Treatment A reefs and the apparent increase on both Treatment B and the control reefs between t = 0 and t = 12 mo suggest that the treatments were not responsible for any increase in mean juvenile coral density and that natural variability is a more likely explanation.

The decline in coral cover and vitality in Treatment A quadrats observed during this investigation can be attributed to active tissue necrosis resulting from at least two coral diseases/disease states, and to a lesser degree to macroalgal-related stress (e.g., abrasion, shading, and sediment stress). The active tissue destruction of the few remaining medium-to-large coral colonies by White Plague and Red Band Disease, combined with macroalgal overgrowth-associated tissue mortality, suggests continued decline in the vitality of the experimental site coral community.

Examination of the permanent quadrat video frames as well as observations made throughout the study also provide evidence of potentially significant infestation of coral heads by the boring sponge, *Cliona* sp. If, in fact, the incidence and severity of clionid sponge infestation on the experimental reefs were anomalously high, it could have been an indication of excess nutrient input (Rose and Risk 1985; Ward-Paige et al. 2005) and/or the result of the opportunistic infestation of colonies weakened or freshly killed by bleaching, disease, or other sources of stress (Schonberg and Wilkinson 2001).

The effectiveness of the combined treatment of macroalgal reduction and *D. antillarum* addition was likely limited by poor *D. antillarum* survivorship and may have been obscured by the onset of environmental factors more favorable to increased macroalgal growth. Despite restocking the experimental reefs with urchins five months after the initial treatment, none remained at the termination of the experiment. Based on the limited distribution and foraging of *D. antillarum* observed in other studies as a result of high levels of predation pressure (Carpenter 1984; Levitan and Genovese 1989), the urchins were expected to remain on the experimental reefs. Even when food supply is limited, *D. antillarum* tend to avoid the risks associated with migration and instead have the ability to reduce test growth rates and test size in more severe food-limited situations (Levitan 1988).

The low *D. antillarum* survivorship rates observed in this study are similar to those observed in a recent study that involved enclosing aggregates of wild *D. antillarum* around individual coral colonies in an attempt to improve the substrate quality for coral reseeding efforts and supplementing local *D. antillarum* populations with lab-reared individuals and monitoring their survivorship (The Nature Conservancy 2004). *Diadema antillarum* mortality was high in both components of the study, with approximately two-thirds of the enclosed wild urchins lost within the first 3 to 6 months of the project and 100% of the lab-reared urchins lost between 24 hours and several weeks after their release. Predation was cited as the major source of the high mortality levels in both cases. Despite the low urchin survivorship observed in the Nature Conservancy (2004) study, high levels of algae biomass were removed by the wild urchins and coral spat were observed several months after collected coral spawn were seeded on the primed substrate.

In contrast to the low *D. antillarum* survivorship observed in this investigation and in the Nature Conservancy (2004) study, Nedimyer and Moe (2003) observed considerably greater survivorship (30% remained after 11 mo) in a similar effort that involved translocating juvenile *D. antillarum* from high settlement/high mortality reef crest rubble zones to deeper patch reefs. The significantly greater *D. antillarum* survivorship in the Nedimyer and Moe (2003) study was likely one of the major factors that contributed to the increased scleractinian coral cover, decreased macroalgal cover, and the increased juvenile coral density observed on their experimental reefs a year after the urchin additions.

The low *D. antillarum* survivorship observed in this study may have been controlled by several factors, such as the potential lack of suitable refugia, the presence of more robust populations of *D. antillarum* predators, or a combination of factors. The patch reefs used by Nedimyer and Moe (2003) were between 44 and 96 m^2, and may have provided more suitable urchin refugia.

In addition to the substantially greater *D. antillarum* survivorship observed in the Nedimyer and Moe (2003) study, the difference in benthic community compositions between the two sets of reefs prior to treatment may also have influenced the differing outcomes of *D. antillarum* additions of the Nedimyer and Moe (2003) study and this investigation. For example, scleractinian coral cover on the Nedimyer and Moe (2003) reefs was significantly higher (ranging from 5.5-14%, mean of 9.8%), while coral cover on the reefs examined in this investigation ranged from 0.7 to 5.6%, with a mean of 1.9%. Mean algae cover on the Nedimyer and Moe (2003) reefs was 54.3%, with well over half of the total algae cover on all reefs consisting of turf algae. Brown foliose algae cover ranged from 9-11%, while green foliose algae was less than 1% on all of the Nedimyer and Moe (2003) reefs. In contrast, macroalgal cover alone (not including turf algae) on the reefs in this study ranged from 37.2-71.0%, with a mean of 58.2%.

Also, *Microdictyon marinum* was not mentioned in the Nedimyer and Moe (2003) study. If it was present at all, it was only a minor component of the benthic community. This is in stark contrast to the dominance of *M. marinum* on the reefs of this study, which may have had a strong influence on the effect of the

experimental treatments. The rapid growth of *M. marinum* and the high canopy height achieved by the species may have a more profound affect on coral survivorship than other algae species. Its rapid growth, in combination with the poor survivorship of *D. antillarum*, may also have prevented the maintenance of an algal turf by overwhelming the urchins and the herbivorous fish. It is also interesting to note that although Nedimyer and Moe (2003) did not utilize macroalgal reduction to "prep" the substrate for the addition of *D. antillarum*, significant decreases in macroalgae and increases in coral cover were still observed on the experimental reefs.

Conclusions and Recommendations

The results of this study suggest that the proposed restoration technique in its present form was not effective at significantly reducing macroalgal re-growth or enhancing juvenile coral recruitment. The unexpectedly high flight and/or mortality rates for the translocated *D. antillarum* individuals are the most likely explanations for the less-than-expected performance of the restoration technique. One would expect a persistent *D. antillarum* population to be able to maintain an algal turf and prevent macroalgal re-growth, but the number of urchins needed to sustain such a population in the face of high flight/mortality rates would require a considerable supply of urchins and considerable human effort. Survivorship may be greater at other sites, as Nedimyer and Moe (2003) observed, and thus the success of the treatment may vary from site to site as a function of urchin predation levels, availability of suitable refugia, or some other factor.

Future restoration efforts using *D. antillarum* may benefit from abandoning patch reefs of such small sizes in favor of larger patch reefs – perhaps those with an area of 25 to 50 m^2. The larger size may enhance *D. antillarum* survivorship by providing more refugia. Macroalgal reduction on patch reefs of this size would still be feasible with a relatively small number of divers.

The development of a restoration technique involving macroalgal reduction and the addition of *D. antillarum* that was more successful at reducing macroalgae and increasing adult coral cover and juvenile coral density could be used concomitantly with efforts to manage local anthropogenic threats. Efforts to reduce anthropogenic impacts to coral reefs on a local level, and the implementation of localized restoration efforts should be continued and can be considered attempts at restoring to the reef-building corals the resilience required to acclimate or adapt to rapidly changing environmental conditions.

Benthic colonization and ecological successional patterns on a planned nearshore artificial reef system in Broward County, SE Florida

A. Carter, S. Prekel

Marine Science & Biological Research, CPE, 2481 NW Boca Raton Blvd, Boca Raton, FL 33431

Abstract. Nearshore marginal reefs are frequently impacted from beach restoration activities. Beach nourishment can impact nearshore hardbottom through burial and subsequent habitat degradation. In response to increased beach nourishment activities, reef restoration projects have increased immensely over the last decade. In Southeast Florida, the deployment of artificial reefs (ARs) as mitigation for nearshore habitat loss has become routine. To determine the success of ARs as appropriate nearshore habitat replacement, long-term AR colonization studies are essential to evaluate ecological processes and succession rates in shallow marine environments. This paper reports on the development, recruitment and ecological succession rates of macrobenthic communities on a mitigative AR system located in Broward County, Florida. Pioneering organisms and community composition were evaluated via the Coastal Planning & Engineering, Inc. Benthic Ecological Assessment for Marginal Reefs (BEAMR) method. Benthic communities were sampled at 9-, 12-, 18-, 24-, and 36-month post-deployment. Both spatial and temporal fluctuations of colonizing organisms were assessed, as well successional stages of contemporary organisms. Results indicated a typical colonization pattern where biotic cover and diversity increased on the AR system progressively from 9 to 36 months post-deployment; however, equilibrium was not attained at the functional group level due to frequent physical disturbances.

Key words: Artificial reef, community development, recruitment, macrobenthic communities, functional group.

Introduction

Beach nourishment can impact nearshore hardbottom through burial and subsequent habitat degradation. In response to increased beach nourishment activities, reef restoration projects have increased immensely over the last decade. In southeast Florida, the deployment of artificial reefs (ARs) as mitigation for nearshore habitat loss has become commonplace. To determine the success of ARs as appropriate nearshore habitat replacement, long-term AR colonization studies are essential to evaluate ecological processes and succession rates in shallow marine environments (Cummings 1994; Perkol-Finkel and Benayahu 2005; Thanner et al. 2006).

Understanding the spatial and temporal fluctuations of colonizing organisms is essential in forecasting benthic community development on ARs. Classic models of colonization suggest a directional successional sequence where pioneering species rapidly colonize the substrata in high numbers followed by a more diverse climax community (Bailey-Brock 1989; Cummings 1984; Palmer-Zwahlen and Aseltine 1994; Stanos and Simon 1980). Alternatively, Sutherland and Karlson (1977) suggest that classic succession cannot be evaluated with a new AR system as recruitment is determined by stochastic larval recruitment and the relative dominance of pioneer species. Additionally, biological habitat complexity is an important factor pertaining to larval settlement and species composition; thus, only after a temporal community shift will additional species have the opportunity to settle onto suitable habitat (Connell and Slather 1977).

In 2003, approximately 9 acres (3.6 ha) of limestone boulders were deployed in 5-m water depths between Florida Department of Environmental Protection (FEDP) R-monuments 101 and 125. The diameter of each boulder was 1.2-1.8 m. The limestone boulders, acquired from a Grand Bahamian quarry, were placed in a single layer on hardbottom areas covered with approximately 0.9 m of sand. The distance between individual boulders did not exceed 2.1 m. This study reports on the biotic community development and ecological succession patterns on this AR system located in Broward County, Florida (Fig. 1).

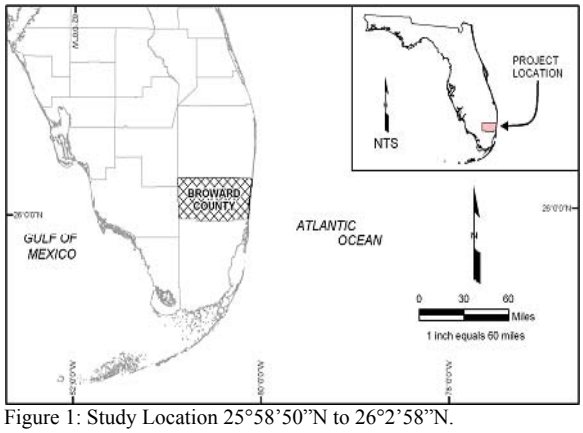

Figure 1: Study Location 25°58'50"N to 26°2'58"N.

Material and Methods

Benthic community composition was measured 9, 12, 18, 24 and 36 months after deployment using the Coastal Planning & Engineering, Inc. Benthic Ecological Assessment for Marginal Reefs (BEAMR) method (Lybolt and Baron 2006). A component of the BEAMR protocol includes a standardized BEAMR datasheet which prompts biologists to complete all fields *in situ* and strengthens quality assurance (Fig. 2).

Figure 2: Example of a completed BEAMR datasheet.

BEAMR samples three core characteristics in each quadrat: physical; abiotic and biotic percent cover; and coral density. Physical characteristics recorded are maximum relief in the quadrat (to nearest cm) and maximum sediment depth (to nearest cm). Visual estimates of planar percent cover of all sessile benthos are pooled to 19 major functional groups. Macroalgae percent cover data are reduced to genus-level percent cover (all genera with at least 1% cover). Each colony of octocoral and stony coral is identified and the maximum height or width is measured to the nearest cm. Octocoral individuals are identified to genus and stony coral individuals are identified to species whenever possible. The smallest size recorded is 1 cm, which includes individuals less than or equal to 1 cm. As with all non-consumptive surveys, BEAMR is necessarily constrained to visually conspicuous organisms with well defined discriminating characteristics for identification.

A total of 26 transects were sampled at each monitoring event. Prior to benthic data collection, stainless steel pins were installed on each transect at 0, 1, 5, 10, 15, 20, 25, 29, and 30 m to ensure permanent sampling sites. BEAMR was conducted on the north side of each 30-m transect using 12 replicate 1.0-m^2 quadrats (1 m x 1 m) every 2.5 m, starting at 0.0-m. The southwest corner of each BEAMR quadrat was aligned with the precise point of the sample location.

Non-parametric multivariate analyses were performed using PRIMER-E® (v6) (Clarke and Gorley 2006; Clarke and Warwick 2001). The biotic dataset was standardized by total and transformed by a log (X+1) transformation. A Bray-Curtis similarity matrix was also applied. Multi-dimensional scaling (MDS) ordinations and analysis of similarity (ANOSIM) routines were derived from the Bray-Curtis similarity matrix to determine if significant changes in the biotic assemblage occurred over time. Diversity indices were also comparatively analyzed.

Results

The biotic benthic community of the artificial reef was analyzed in order to determine recruitment patterns. Fig. 3 presents the biotic community on the artificial reef at the five discrete monitoring times. Turf algae was the dominant taxon over time. Of the faunal functional groups, sponges (16.4%), bryozoans (4.9%), tunicates (3.4%), and hydroids (2.2%) were highest during 9-month post-deployment but decreased sharply thereafter.

Sponge average percent cover decreased after 9 months and remained at approximately 5% for the remaining monitoring events. Scleractinian corals and *Millepora* spp. demonstrated the most consistent increase in abundance over time (Fig. 3).

A similarity percentages (SIMPER) analysis identified discriminating functional groups between each monitoring survey. Between 9-month and all subsequent monitoring surveys, bryozoans and

macroalgae were the primary contributors to the dissimilarity (Fig. 4).

	9-month	12-month	18-month	24-month	36-month

Figure 3: Biotic community composition (n=26) at 9-, 12-, 18-, 24- and 36-month post-deployment.

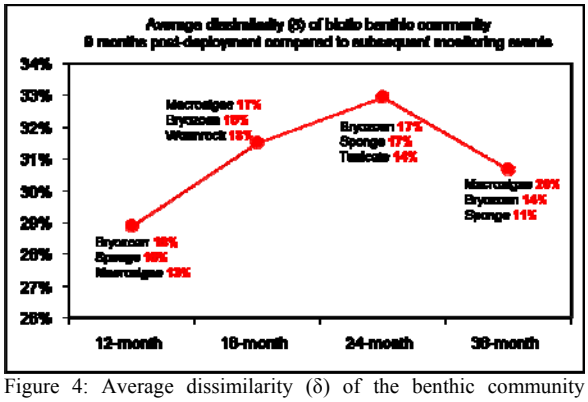

Figure 4: Average dissimilarity (δ) of the benthic community between the 9-month and subsequent monitoring events. Percentages of the major contributors to δ are listed at each event.

Initially bryozoan cover was relatively high at 4.9% but decreased rapidly 3 months later to less than 1% where it remained consistently thereafter. Macroalgae cover increased consistently until 24-month where percent cover decreased to less than 3% (refer to Fig. 3). However, macroalgae percent cover rebounded to almost 16% at the 36-month monitoring event. Stony coral became a dominant contributor (8.8%) to the community dissimilarity between 12 and 36 months.

Non-parametric multivariate analyses were applied to the functional group dataset to further examine changes in biotic composition over time. A MDS ordination with cluster overlay indicated a distinct difference between the biotic assemblage at 9-month post-deployment compared to subsequent monitoring intervals (Fig. 5). However, the functional group assemblages remained at least 75% similar throughout all monitoring surveys. Additionally, results of a 1-way ANOSIM revealed the 24-month post-deployment biotic community most closely resembled the 12-month community (R=0.273). This similarity correlates with the decrease in macroalgae cover from 12.7% at 18-month to 2.8% at 24-month (see Fig. 3). The 1-way ANOSIM also revealed the strongest biotic differences existed between 9- and 36-month assemblages (R=0.677), and between the 24- and 36-month assemblages (R=0.655).

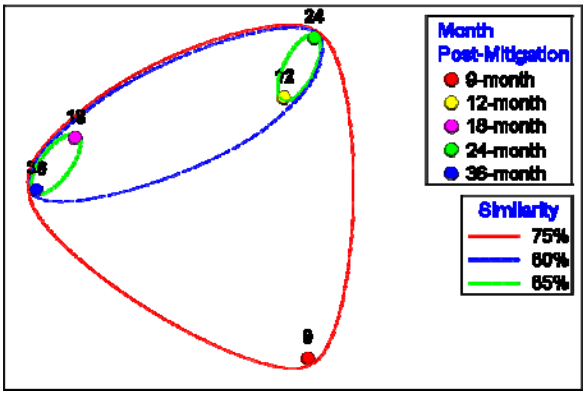

Figure 5: MDS ordination based on Bray-Curtis similarity of the biotic assemblages on the artificial reef at 9-, 12-, 18-, 24-, and 36-month post-deployment (stress = 0.1).

Diversity indices were calculated on the non-transformed data at each monitoring survey utilizing PRIMER (Table 1). The overall trend showed an increase in community diversity over time.

Table 1: Diversity indices of the biotic benthic community over time.

	No. of Functional Groups (S)	Margalef's (d)	Pielou's (J')	Shannon's H' (loge)	Simpson's (1-d)
9-month	16	5.93	0.69	1.92	0.86
12-month	15	5.87	0.68	1.85	0.85
18-month	16	6.93	0.72	1.99	0.88
24-month	14	5.62	0.71	1.87	0.84
36-month	16	5.72	0.77	2.12	0.90

The macroalgae community was analyzed to determine which genera were the initial colonizers and successive genera (Fig. 6). *Padina* spp. had the

highest percent cover at 9-month (3.7%) while *Wrangelia* spp. dominated the substrate at 36-month (76.7%). *Dasya* spp. was most prevalent at 18-month (55.2%), which was the only winter survey.

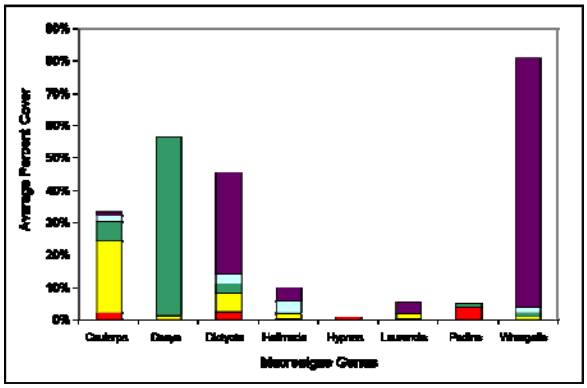

Figure 6: Average percent cover of dominant macroalgae genera over time.

The octocoral and stony coral community were also analyzed to determine the initial colonizers and successive genera (Fig. 7).

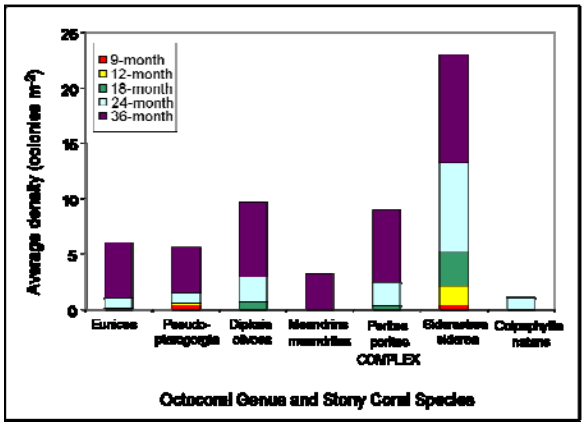

Figure 7: Density of dominant octocoral genera and coral species over time.

Overall two soft coral genera dominated with *Pseudopterogorgia* spp. initially recorded at the 9-month monitoring event while *Eunicea* spp. were recorded, at a very low density, during the 12-month monitoring event. Of the scleractinians, *Siderastrea siderea* was the only pioneer species recorded during the 9-month survey. *Siderastrea* spp. are considered one of the most stress tolerant species found in southeast Florida (Lirman et al. 2002). Four additional scleractinian species dominated during the subsequent monitoring events including *Diploria clivosa, Meandrina meandrites, Porites porites* complex, and *Colpophyllia natans*. *D. clivosa* and *P. porites* were initially recorded at the 18-month survey, while *C. natans* was first recorded at the 24-month event. *M. meandrites* was only documented during the 36-month post-deployment monitoring survey.

Discussion

The three year study of benthic community development showed a series of biotic changes over time. Initial colonizers on the Broward County AR system consisted of typical fouling organisms such as bryozoans, hydroids, sponges and tunicates. Bryozoans and hydroids are known fouling organisms which are often replaced over time in biotic succession (Abdel-Aleem 1957; Otsuka and Dauer 1982; Palmer-Zwahlen and Aseltine 1994). As the AR substratum was biologically altered and became more complex over time, the benthic community differentiated further. Results demonstrate that a large percentage of these pioneering organisms were replaced by more persistent and biologically complex organisms, *i.e.* scleractinians and octocorals, as the AR "soak" time increased. This ecological successional pattern is supported by overall increasing trends in diversity indices.

As of 36-month post-deployment, bryozoan percent cover decreased by 4%, tunicate percent cover decreased by 2.6%, sponge percent cover decreased by 10.4%, and hydroid percent cover decreased by 1.7%.

Fouling organisms are essential in elevating the habitat complexity of AR systems, thus making it suitable for coral settlement (Perkol-Finkel and Benayahu 2005; Schuhmacher 1988) and a large increase in octocoral and coral density over time was evident. However, while this increase may be attributed to scleractinians' preference to settle on a complex substratum rather than simple one (Carleton and Sammarco 1987; Guichard et al. 2001), coral larvae tend to remain inconspicuous upon settlement (Edmunds 2000). Hence, coral recruits present at the 9-month monitoring survey may not have been visually conspicuous and were, therefore, not accounted for until the 12-month post-deployment survey.

Results indicate a shift in community composition over time; however, a classic directional successional pattern was not evident. As the MDS ordination of the biotic community over time suggests, and the ANOSIM results confirm, a strong similarity between the 12- and 24-month assemblages occurred, while a strong difference was detected between the 24- and 36-month assemblages.

Considering that succession did not proceed in a classic directional pattern beyond 18 months post-deployment may be due to the frequent physical disturbances present in the area during 2005. Two hurricanes affected the Broward County coastline immediately preceding the 24-month monitoring

survey. Both Hurricane Dennis and Katrina elevated wave frequency and heights resulting in extreme impacts to the nearshore coastline during July and August 2005. This included intense sand inundation and scouring. Eradication of the existing biota on the AR system may be correlated to these disturbances including the significant decrease in the total macroalgae percent cover. Macroalgae cover increased consistently until the 24-month monitoring event when it was then reduced by a total of 9.9%. Macroalgae cover rebounded post-hurricane by a total of 12.8%, as observed during the 36-month monitoring survey.

Unlike macroalgae, stony coral average percent cover increased consistently throughout this study suggesting that the high relief of the AR system may have provided protection from burial associated with storm activity.

In summary, community structure exceeded an initial developmental stage. Colonization of the AR system investigated in this study can be explained only partially in terms of classic directional succession as physical disturbances impeded progress to a possible climax community.

Effects of herbivore grazing on juvenile coral growth in the Gulf of Mexico

S.W. Davies and P.D. Vize

Department of Biological Sciences, University of Calgary, 2500 University Drive NW, Calgary, Alberta, T2N 1N4, Canada

Abstract. This study demonstrates how herbivore grazing and substrate variations influence coral recruitment patterns at the Flower Garden Banks, Gulf of Mexico, for two brooding corals, *Agaricia spp.* and *Porites spp.* Three herbivore treatments and two tile textures and orientations were tested. Herbivore grazing significantly affected coral growth for *Agaricia,* but had no effect on *Porites*. Data suggest that grazing of *Diadema antillarum* and *Cerithium litteratum* negatively affected growth of juvenile *Agaricia* since smaller colonies were observed in herbivore treatments ($p=0.0034$). *Agaricia* recruits were larger on rough textured tiles ($p=0.0054$), but tile texture did not affect *Porites* size. Tile orientation preference differed between species, with *Agaricia* having larger and more colonies on vertical tiles ($p<0.0001$) whereas *Porites* colonies were larger and more numerous on horizontal tiles ($p=0.0053$). Our findings suggest that recruitment and growth of corals varies considerably between species and that this needs to be considered when developing reef conservation strategies.

Keywords: Herbivory, coral recruitment, *Diadema antillarum,* phase shifts

Introduction

Competition for primary space plays a major structuring role on coral reefs (Lang and Chornesky 1990) and phase shifts from coral to algal dominated communities highlight the importance of this competition. Reports of declining reef resilience and phase shifts towards algal dominated communities appear to be increasing at an accelerated rate (Done 1991; McCook et al. 2001; Hughes et al. 2003, 2007; Aronson and Precht 2006). Caribbean reefs have experienced an average of 40% coral loss since the 1970's (Gardner et al. 2003) and exhibit little recovery as recruitment rates decrease. Many factors affect coral recruitment, however algal competition appears to play a significant role in inhibiting recruitment and growth (McCook et al. 2001; Lirman 2001; Jomba and McCook 2002; Birrell et al. 2005; Vermeij 2006).

Grazing has been suggested as a tool to mitigate coral recruitment since herbivore exclusion experiments have demonstrated that reduced grazing causes declines in coral cover (e.g. Lirman 2001) and increasing grazing creates more suitable substrate on which corals can recruit (Omori *et al*. 2006). Caribbean reef communities appear to be highly influenced by the echinoid species, *Diadema antillarum* (Sammarco 1980; Carpenter 1988, Carpenter and Edmunds 2006), which was profoundly demonstrated in 1982 when a natural, species-specific pathogen induced a mass mortality of *D. antillarum* across the entire Caribbean. Mortality rates reaching 99% were observed (Lessios et al. 1984) and reefs were taken over by robust algal species, which caused a decrease in coral recruitment (Hughes et al. 1989). The recovery of *D. antillarum* has been remarkably slow; however, an increase in juvenile coral recruitment has been associated with urchin resurgence in Jamaica suggesting that these herbivores are a keystone species for coral growth (Carpenter and Edmunds 2006).

The Flower Garden Banks National Marine Sanctuary (FGB) (Fig.1) is an ideal area to study coral recruitment and competition, not only for its pristine conditions, but also for its relatively low species diversity (Gittings, 1992), which offers a simpler approach to understanding the ecology of the system. This study investigates how herbivores influence early coral recruitment and growth in the Gulf of Mexico.

Figure 1: Map the Gulf of Mexico showing the location of the Flower Garden Banks National Marine Sanctuary, 115 miles south of the Texas/ Louisiana border.

Recruitment rate variations can have profound repercussions on the management of coral reefs and low coral recruitment rates currently being observed on Caribbean reefs are likely to result in slow reef recovery after natural or anthropogenic disturbances (Hughes et al. 1999). Using herbivorous species to promote recruitment has been suggested as a solution to reduce the long-term decline of coral communities (Hughes et al. 2005; McCook et al. 2001).

Material and Methods

Experimental setup

A 6m x 6m x 0.6m galvanized steel platform was constructed in June 2007 on a sand patch at 24m depth on the East FGB (27º54'33.0"N, 93º35'59.7"W, Fig.2) to provide a controlled environment to test the effects of herbivores and tile texture and orientation on coral recruitment and growth. Nine fiberglass bins (117cm x 36cm x 25cm), each randomly assigned to one of three treatments (1. *Diadema antillarum*; 2. *Cerithium litteratum*; 3. No herbivore control), were attached. Twelve quarry tiles (15cm x 15cm) were suspended within each bin and served as settlement substrata. Tiles had one smooth side and one grooved side (Smooth, Rough) and two orientations (Vertical, Horizontal) were tested. Herbivore densities within treatments were determined by conducting herbivore censuses of the surrounding reef area and two *Diadema antillarum* and 50 *Cerithium litteratum* per bin were used. All animals were collected at night using SCUBA and retained within bins using 1.3cm^2 wire mesh.

Figure 2: Coral recruitment platform constructed on a sand patch on the East Flower Garden Banks at 24m depth.

Data analysis:

In April 2008, after nine months of natural recruitment, four tiles from each bin were photographed using a high-resolution digital underwater camera with strobe. All recruits (live and dead) were divided by genus (*Porites, Agaricia*) and total polyp/colony area (mm^2) was directly measured in ImageJ 10.2 and compared between herbivore treatments, tile textures and tile orientations. Coral size data were log-transformed to satisfy the assumptions of normality (Shapiro-Wilk) and equal variances for parametric statistical tests. Only main effects are presented here as no significance was observed for interaction terms. All statistics and graphics were performed in JMP 7.0.2.

Results

Herbivore treatment

Herbivory significantly affected colony size for *Agaricia* (p=0.0034) but not *Porites* (p=0.4445, Fig.3B) (Table 1). *Agaricia* recruits were the smallest in the sea urchin treatment, larger in the mollusk treatment and the control treatment had the largest recruits (Table 2, Fig.3A).

Table 1: Analysis of variance (ANOVA) table indicating variation coral size (mm^2) (log-transformed) for *Agaricia spp.* and *Porites spp.*

Source	DF	F Ratio	P
Agaricia spp.

Table 2: Tukey's Studentized Range (HSD) test for significant differences in coral size (mm^2) (log-transformed) between different herbivore treatments.

	Tukey Grouping*	Least Sq Mean	Std Error	n
Agaricia α=0.05				**489**
Control	A	2.56	0.10	175
Mollusk	B	2.03	0.11	149
Urchin	C	1.77	0.10	165
Porites α=0.05				**78**
Control	A	2.33	0.20	29
Mollusk	A	2.65	0.20	31
Urchin	A	2.31	0.32	18

*Levels not connected by the same letter are significantly different

Tile texture

Tile texture had a significant effect on coral size for *Agaricia* (p=0.0054), however there was no texture effect for *Porites* (p=0.8393, Fig.4B) (Table 1). Student's t-tests demonstrated that *Agaricia* recruits on rough surfaces were significantly larger than those growing on smooth surfaces and there were also approximately three times as many recruits on rough surfaces (Table 3, Fig.4A)

Table 3: Student's t-test results for differences in coral size (mm^2) (log-transformed) between different tile textures and orientations.

	Least Sq Mean	Std Error	n
Agaricia			**489**
TEXTURE*			
Smooth	1.97	0.10	127
Rough	2.29	0.06	362

ORIENTATION*			
Horizontal	2.88	0.12	63
Vertical	1.98	0.27	15

*Indicates significant difference α=0.05

Orientation

Tile orientation significantly affected colony size for both *Agaricia* (p<0.0001) and *Porites* (p=0.0053) (Table 1), however, opposite trends were observed. *Agaricia* colonies were larger on vertical tiles and were approximately 2.5 more numerous on vertical tiles (Table 3, Fig.5A). *Porites* colonies were larger and over four times more numerous on horizontal tiles (Table 3, Fig.5B).

Discussion

This study on juvenile coral growth at the FGB demonstrates that herbivore and substratum variations can have significant effects on recruitment and that these effects vary between coral species. Two types of corals were observed to recruit, *Agaricia* and *Porites.* Both corals are brooders, where fertilization occurs within the polyp and released larvae are competent to settle almost immediately (Harrison et al. 1984). It is important to note that although these brooding coral species observed here are common on the FGB, they are not the dominant coral species. Coral cover at the FGB is dominated by other scleractinian corals, which reproduce annually in mass spawning events. The results observed here are representative of only one site in the Gulf of Mexico and caution needs to be taken when comparing these results to other coral species and reefs.

Coral recruitment is variable and larvae actively choose suitable substrate on which to settle. Space pre-emption by other benthic organisms can therefore lead to a decrease in local coral recruitment (Vermeij 2006). Research suggests that corals have inferior competitive capabilities and slower growth rates relative to other benthic organisms such as algae, which have been shown to smother young coral recruits (Miller and Hay 1998; Connell 1997; Edmunds and Carpenter 2001; Vermeij 2006). The top-down control of herbivore grazing on algal growth has been previously demonstrated (Carpenter and Pace 1997; McCook 1999) leading to the general hypothesis that herbivores may reduce competition, thereby increasing coral growth.

In this study we found that urchin grazing negatively affected coral growth for *Agaricia* but had no significant effect on *Porites* (Fig 3AB). Birrell et al. (2005) found that coral recruits almost exclusively preferred to settle on surfaces free from sediment and algae. Although urchin grazing has been correlated with increased coral recruitment (Carpenter and Edmunds 2006), we found that coral colony growth was significantly decreased in the sea urchin treatment, indicating that our experimental sea urchin levels resulted in destructive overgrazing. Destructive overgrazing occurs when echinoid densities are high and algal grazing becomes competitive and abrasive causing a reduction in coral growth (Sammarco 1980). For *Agaricia,* coral recruits were the largest in the control, which was not expected as most herbivore exclusion experiments have shown that when algae are released from grazing pressures, algal growth and coral mortality both increase (Sammarco 1980; Tanner 1995; Lirman 2001; Jomba and McCook 2002; Birrell *et al*. 2005). These unpredicted control results are most likely due to invasive herbivores recruiting to the control bins over the winter months. Several sea urchins were observed to recruit into all experimental bins, however this recruitment is presumed to be equal across all treatments.

Substrate texture has been shown to have a strong effect on juvenile corals. Peterson et al. (2005) found corals demonstrated a strict preference towards grooves in tiles and Harrison and Wallace (1990) indicated settlement and metamorphosis were generally favored in crevices as well. In this study we demonstrated that texture preference might be species specific. *Agaricia* experienced higher growth rates on rough textured tiles while *Porites* showed no significant difference. However, both species had more recruits on rough textured tiles (Table 3) and this is most likely due to the grooves providing sanctuary for corals from overgrazing and overgrowth by other encrusting species.

Research suggests that scleractinian corals show clear preferences for substrate position. Babcock and Mundy (1996) found that coral settlement on the undersurfaces of tiles was much higher, while Vermeij (2006) found higher survival rates on vertical surfaces. In this study we found that the effect of tile orientation on coral growth was highly species specific. *Agaricia* preferred vertical tiles with almost three times as many corals on vertical tiles and significantly larger sizes as well (Fig.5A). *Porites,* however, showed a higher affinity for horizontal tiles with significantly larger individual sizes and over five times as many recruits (Fig.5B). Vermeij (2006) has suggested that variations in orientation preference may stem from differences in growth rates. Faster growing species prefer open, exposed habitats while slower growing species prefer cryptic habitats because the faster growing corals may be more dependent on the symbiotic zooxanthellae in their tissues. During storms sand accumulated on horizontal tiles, which may have affected recruitment.

The distribution and abundance of corals reflect the patterns of successful recruitment and long-term mortality. Coral settlement and growth is not random but dependent on factors such as light, water circulation, sedimentation, competition, predation and grazing (Rogers *et al.* 1984). Monitoring coral growth is important since mortality rates decrease considerably as coral recruits increase in size (Wilson and Harrison 2005). Since recruitment is crucial for coral population maintenance, any disruption in coral reproductive output will eventually lead to long-term declines (Hughes and Tanner 2000; Nozawa *et al.,* 2006). By gaining a more comprehensive understanding of coral recruitment and competition dynamics, research will offer important insights for conservation strategies and management decisions of coral reefs.

Settlement behavior of *Acropora palmata* planulae: Effects of biofilm age and crustose coralline algal cover

P.M. Erwin, B. Song, A.M. Szmant

UNC Wilmington, Center for Marine Science, 5600 Marvin K. Moss Ln, Wilmington, NC 28409, USA

Abstract. The role of crustose coralline algae (CCA) and bacterial biofilms in the settlement induction of *Acropora palmata* larvae was tested with ceramic tiles conditioned in reef waters for different time periods. Larval settlement varied among tiles by conditioning time (P<0.001), with low settlement (11%) on unconditioned tiles and high settlement (72-87%) on tiles conditioned for 2, 8 and 9 weeks. Tile surface texture and orientation also affected settlement (P<0.001). Larvae of *A. palmata* preferred the undersides of tiles as conditioned in the field (78% of total settlement), compared to upper surfaces (8%) or Petri dish surfaces (14%). CCA cover increased with conditioning time (P<0.001) and differed by tile orientation (P<0.005), revealing a positive correlation between settlement and CCA cover on tile bottoms, but not tile tops. Terminal restriction fragment length polymorphism (T-RFLP) analysis of 16S rRNA genes revealed that biofilm age, tile surface and tile orientation affected microbial community structure. Further, biofilms that induced settlement were characterized by bacterial populations distinct from non-inductive biofilm communities. Thus, we present additional evidence of the involvement of CCA and bacterial biofilm communities in the process of coral larval settlement, suggesting that complex interactions among multiple cues are involved in larval settlement choices.

Key words: *Acropora*, settlement cues, microbial community, T-RFLP, crustose coralline algae

Introduction

Scleractinian corals are the foundational organisms that provide coral reefs with the habitat complexity that makes them amongst the most biologically diverse of marine ecosystems. For coral reefs to form, many species of corals must dominate the reef substrate and occupy space over long evolutionary time periods. This must involve both long-lived adult corals and persistent high rates of coral recruitment success on new substrates following disturbances.

Coral recruitment begins with the attachment of a coral planula larva to reef substrate and is successful when the environment into which the larva settles supports its long term survivorship. Conditions favoring coral recruitment success include low competition with faster growing algae and encrusting invertebrates, promoted by high rates of grazing (Hughes 1994; Carpenter 1997; Hixon 1997; Birrell et al. 2005). However, coral larvae are structurally simple and have limited ability to sense the environment, except through chemosensory means.

The current view of coral settlement is that when competent planulae explore the reef substrate, contact with certain chemical cues triggers them to stop swimming, attach to the substrate and develop into the primary polyp (reviewed in Harrison and Wallace 1990). These cues are thought to be chemicals associated with or secreted by crustose coralline algae (CCA) or microbes growing on the substrate. Chemical extracts from certain species of CCA have been demonstrated to induce coral settlement more strongly than others, indicating preference and specificity for cues associated with those species (Morse et al. 1988, 1996; Morse and Morse 1991, Heyward and Negri 1999, Harrington et al. 2004). However, settlement experiments conducted on *Montastraea faveolata* and *Acropora palmata* revealed that most larvae settled near, rather than on, CCA patches (Szmant and Miller 2005). A more recent, detailed study found that over 80% of the larvae from these coral species attached onto microbial films (Nugues and Szmant in prep.), suggesting that microbial communities may be responsible for generating the settlement signal. Indeed, studies have demonstrated the induction of larval settlement by bacteria, including a cultured isolate from CCA (*Pseudoalteromonas* sp. strain A3, Negri et al. 2001) and diverse, naturally-occurring reef biofilm communities (Webster et al. 2004).

Determining the settlement cues of coral larvae is crucial to reef conservation and restoration efforts, allowing for the identification and targeted preservation of high recruitment reef niches, as well as, the direct application of replicated cues to coral nursery programs requiring induction of larval metamorphosis under laboratory conditions.

In this study, we used an experimental approach similar to that described by Webster et al. (2004) to determine the role of CCA and microbial biofilms in larval settlement induction. New substrates (ceramic tiles) were 'conditioned' in seawater to develop natural reef biofilms. The complexity of biotic communities that develop on new substrates increases with field conditioning time, as does their attractiveness to coral larvae (Webster et al. 2004). Tiles were aged from 0 to 9 weeks in a back reef lagoon and used in settlement bioassays. Terminal restriction fragment length polymorphisms (T-RFLP) analysis, a popular culture-independent microbial profiling technique (Schütte et al. 2008), was used to characterize the community structure of microbial biofilms. We present here the correlations between settlement of the larvae of the Caribbean reef coral, *A. palmata*, and these microbial signatures, as well as, the amount of CCA colonizing the tiles.

Material and Methods

Settlement tiles: orientation and texture
Ceramic tiles (high-fired clay, Daltile®) attached to plastic racks on cement blocks were pre-conditioned in the field at 4 m for 2, 4, 6, 8 and 9 weeks. Tiles consisted of a glazed, flat surface and an unglazed, dimpled surface. For each time point, 24 tiles were deployed glazed-side up and 24 glazed-side down. Thus, there were 4 possible combinations of tile surface texture and orientation during field conditioning. Tiles were collected simultaneously in individual bags the day settlement experiments were conducted. Control tiles were soaked in 5µm filtered seawater (FSW) overnight.

Gamete collection and larval rearing
Gamete bundles were released by *A. palmata* colonies during the night of September 1, 2007. Spawn from multiple colonies were collected, cross-fertilized and reared to the planulae stage (Szmant and Miller 2005).

Settlement assay
Large Petri dishes (150 mm x 25 mm) were filled with 200 mL FSW at 29 °C and one tile of each orientation – glazed-side up and glazed-side down, as oriented in the field – were added to each dish. Twenty competent *A. palmata* larvae were added to each dish, with 5 replicate dishes per time treatment. After 48 hours, settled larvae were enumerated on each tile using a dissecting microscope. Following settlement counts, digital photographs were taken of each tile face and sterile cotton swabs were used to sample biofilm communities. Paired T-tests, a 2-way ANOVA and a nested ANOVA (tile texture and tile orientation nested with conditioning time) were run to determine the effects of conditioning time, tile texture and tile orientation on larval settlement using SigmaPlot 11.0 and Statistica (1998 version).

Crustose coralline algae quantification
Digital photographs were processed using ImageJ software (NIH). Quantification of CCA was only possible on glazed tile surfaces, where contrast was high between CCA patches and the tile background. Photographs were cropped to fit the tile surface, CCA patches were defined as regions of interest, and black and white mask images were created. CCA cover was calculated by measuring the dark area of the mask images. A 2-way ANOVA was run to determine the effects of conditioning time and tile orientation on CCA cover. Linear regression analyses were performed to compare CCA cover and larval settlement rates on each tile face (SigmaPlot 11.0).

DNA extraction and amplification
Community DNA was extracted from biofilm swabs preserved in RNAlater (Ambion) using the PUREGENE kit (Gentra Systems) and purified using the Wizard DNA Clean-Up System (Promega). Universal bacterial primers 8F-FAM (Reysenbach et al 1994) and 1522R (Martinez-Marcia et al 1995) were used for amplification of partial 16S rRNA sequences. Total PCR reaction volume was 50 µl, including 15 pmol of the forward primer, 10 pmol of the reverse primer, 25 µl GoTaq® Mastermix (Promega) and 2 µl DNA template. Thermocycler conditions consisted of an initial denaturing time of 5 min at 85 °C, then 35 cycles of 0.75 min at 94 °C, 1 min at 55 °C, and 1.5 min at 72 °C, with a final extension time of 10 min at 72 °C. For each sample, PCR products from 3 separate reactions were combined and gel-purified using the Wizard SV Gel Clean-Up System (Promega). PCR products were quantified using the Quant-iT Qubit® kit (Invitrogen).

Restriction enzyme digestion and T-RFLP analysis
Approximately 100 ng of purified PCR products were digested with the restriction endonucleases *HaeIII* and *MspI*. Total reaction volumes for *HaeIII* digests was 20 µl, including 17.3 µl PCR product, 0.2 µl BSA, 2 µl Buffer C and 0.5 µl enzyme (Promega). Total reaction volume for *MspI* digests was 20 µl, including 17.3 µl PCR product, 0.2 µl BSA, 2 µl NEBuffer 2 and 0.5 µl enzyme (New England Biolabs). All digests were incubated at 37 °C for 12 hours. Immediately following digestion, samples were precipitated with 75% isopropanol and dried (SpeedVac, LabConco). To each sample, 10 µl formamide and 0.5 µl ROX size standard (PE Applied Biosystems) were added. Samples were denatured at 94 °C for 2 min and immediately cooled on ice for 2

min. Samples were analyzed on an automated sequencer (ABI377) with the program GeneScan (PE Applied Biosystems). The length of individual fluorescently-labeled terminal-restriction fragments (T-RFs) was determined by comparison with TAMRA size standards (Genescan™). Raw T-RFLP peak profiles were standardized using a proportional threshold of total fluorescence (Osborne et al 2006) and compared across samples using T-Align (Smith et al 2005). Peak profiles were standardized using relative abundance and peaks with areas <1% of total fluorescence were discarded as background noise.

Non-metric multi-dimensional scaling plots

To assess the similarity of bacterial community structures, Bray-Curtis similarity matrices were constructed using square root transformations of relative abundance T-RFLP data. To visually compare bacterial community similarity across samples and factors, non-metric multi-dimensional scaling (MDS) plots were constructed. Analyses of similarity (ANOSIMs) assessed the statistical significance of similarity among biofilm bacterial communities by the factors tile age, tile surface, tile orientation, and larval settlement. MDS plots and ANOSIM calculations were performed using PRIMER v5.1.2 (Plymouth Marine Laboratory, UK).

Results

Settlement assay

Larval settlement varied significantly over conditioning periods (P<0.001), with low settlement on unconditioned tiles, moderate settlement on tiles conditioned for 4 and 6 weeks, and high settlement on tiles conditioned for 8 and 9 weeks (Fig. 1). Notably, 2-week old biofilms induced settlement levels (72%) similar to the oldest biofilms (8 and 9 weeks), while settlement rates dropped in 4 and 6 week old biofilms.

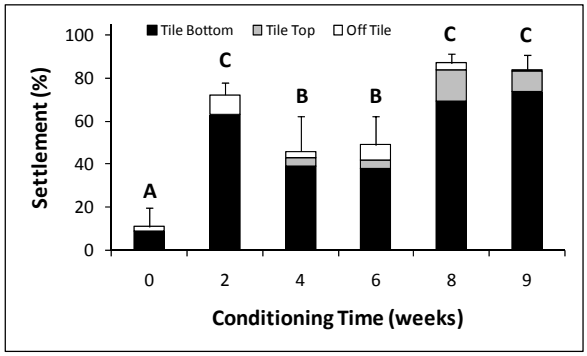

Figure 1. Effect of conditioning time on settlement of *A. palmata* planulae. Black bars represent tile surfaces facing upwards, gray bars tile surfaces facing downwards, and white bars non-tile substrate (Petri dish). Error bars represent 1SD and letters denote significant (P<0.05) differences in total settlement by treatments.

Within conditioning treatments, settlement rates were significantly affected by tile orientation (P<0.05) and tile surface (P<0.05). Total settlement of *A. palmata* larvae showed a clear preference for tile bottoms (78%) compared to tile tops (8%), as oriented in the field, with low settlement (14%) found off tiles.

Crustose coralline algal cover

CCA cover on settlement tiles increased significantly with longer conditioning periods (P<0.001); however, variation within treatments was large. Settlement tiles conditioned for greater than 4 weeks exhibited higher levels of CCA cover than control tiles and tiles conditioned for 2 weeks. CCA cover also varied significantly by tile orientation (P<0.005), with higher cover on tile tops compared to tile bottoms; however, pairwise comparisons within conditioning treatments were only significant for 6-week tiles (P<0.001; Fig. 2).

Linear regression analysis revealed that CCA cover on tile bottoms was positively correlated with larval

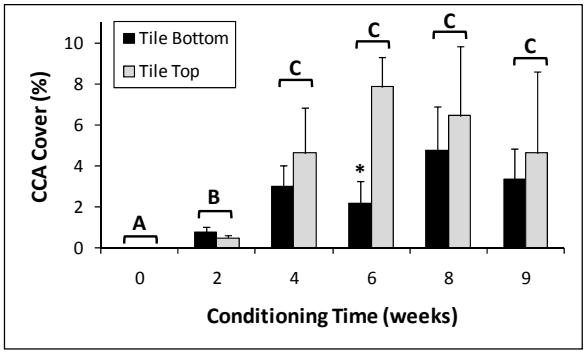

Figure 2. Effect of conditioning time and tile orientation on CCA cover. Black bars represent tile surfaces oriented downwards (bottom) and gray bars tile surfaces oriented upwards (top). Letters indicate significant (P<0.05) pairwise differences among conditioning treatments. Asterisks denote significant (P<0.05) differences among tile bottoms and tile tops within conditioning treatments. Error bars represent 1 SD.

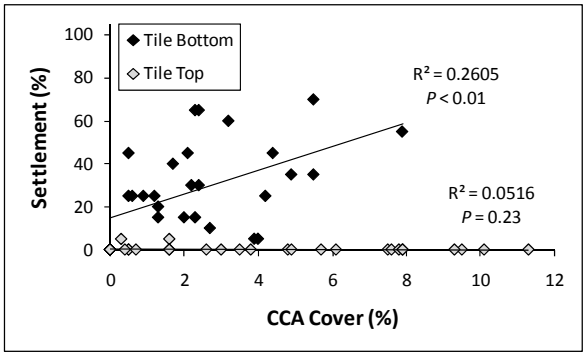

Figure 3. Effect of CCA cover and tile orientation on settlement of *A. palmata* planulae. Dark diamonds denote tile surfaces oriented downward (bottoms) and gray diamonds surfaces oriented upward (tops). Regression lines are shown for tile bottoms and tops.

settlement (P<0.01) and explained 26% of the variation in settlement by *A. palmata* larvae on tile bottoms. However, larval settlement on tile tops was not correlated with CCA cover (P=0.23), despite exhibiting a similar range of CCA cover found on tile bottoms (Fig. 3).

Microbial diversity and biofilm community structure

A total of 47 unique terminal restriction fragments (T-RFs) were identified from 27 T-RFLP profiles analyzed using the restriction endonuclease *MspI*; only 24 T-RFs were identified from 27 T-RFLP profiles using *HaeIII*. Lower resolution with *HaeIII* digestion is likely attributable to excessive digestion of 16S gene sequences, evidenced by short (<60bp), saturated peaks in chromatographs (data not shown).

ANOSIMs revealed distinctions among biofilm bacterial communities based on conditioning periods, tile surface, and tile orientation (Table 1). Distinct bacterial communities were also recovered from tiles inducing settlement compared to non-inducing tiles (*MspI* data). MDS plots exhibited low stress values, indicating congruence between MDS plot and similarity matrix distances. Samples clustered by factors with some overlap among factor levels, representative of the modest R-statistic values reported. MDS plots constructed from T-RFLP analysis with *MspI* showed clearer distinctions among factors compared to *HaeIII* (Fig. 4).

Table 1. ANOSIM summary statistics (R-statistic and *P*-value) for T-RFLP data recovered using *HaeIII* and *MspI*.

	HaeIII		***MspI***	
Factor	R-statistic	*P*-value	R-statistic	*P*-value
Age	0.217	0.002	0.192	0.009
Surface	0.069	0.046	0.210	0.003
Orientation	0.171	0.002	0.305	0.001
Settlement	0.087	0.099	0.186	0.013

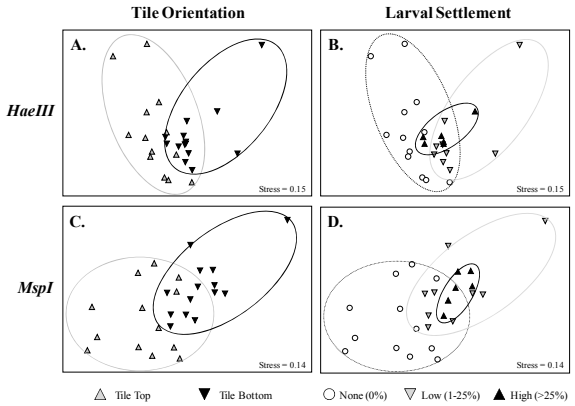

Figure 4. Non-metric multi-dimensional scaling ordination of biofilm bacterial communities recovered by T-RFLP analysis with the restriction endonucleases (A, B) *HaeIII* and (C, D) *MspI*. Data are grouped by (A, C) tile orientation and (B, D) larval settlement induction levels; circles encompass all samples by each factor level.

Discussion

Settlement behavior of *A. palmata* planulae was significantly affected by the conditioning periods of settlement tiles. Both CCA cover and biofilm bacterial communities varied significantly across conditioning treatments, but neither could consistently explain the observed larval settlement preferences. CCA cover correlated with settlement, but only on tiles undersides and accounted for only 26% of settlement variability. Previous work has also reported preferential settlement of coral larvae on the undersides of field conditioned tiles (Babcock and Mundy 1996; Raimondi and Morse 2000; Szmant and Miller 2005; Szmant in prep.). Other studies have reported little effect of CCA presence on larval settlement (Petersen et al. 2005) and settlement of coral planulae in the absence of CCA cues (Negri et al. 2001; Webster et al. 2004). While CCA and non-coralline crustose red algae have been implicated in the induction of coral larval settlement (e.g., Heyward & Negri 1999), settlement cues of crustose algae vary with the algal species and settlement response with different coral species (Golbuu and Richmond 2007). In this study, CCA that colonized settlement tiles may not have represented 'inductive' algal species for *A. palmata* larvae.

Another hypothesis is that the CCA function as part of a multi-cue cascade that leads planulae to settle and metamorphose, in which physical conditions (e.g., low light intensity) or other chemical cues initially attracted larvae to tile undersides, where close or direct contact with CCA surfaces then signals an attractive habitat to the planulae. Indeed, phototactic behavior by coral larvae and increased settlement on tile bottoms under high light intensities has been reported (Mundy and Babcock 1996). In addition, evidence for synergistic interactions among multiple chemical cues derived from CCA that enhance coral larval settlement has been recently reported (Kitamura et al 2007). Clearly, some attribute of tile undersides proved a stronger larval attractant than CCA alone, as CCA were similarly abundant on tile tops where very little to no settlement occurred.

Microbial biofilms play a key role in the settlement induction of many cnidarian larvae (Müller and Leitz 2002), including scleractinian corals (Negri et al. 2001). In fact, 'conditioning' of settlement tiles for microbial biofilms is routinely performed prior to coral larvae bioassays and usually required to achieve high larval settlement. Despite the crucial role of biofilms in larval settlement, few studies have investigated the bacterial community structures established by 'conditioning' (Webster et al. 2004). One recent comprehensive study employed culture-independent molecular and electron microscopy methods to characterize biofilm communities

inhabiting conditioned slides used in settlement assays (Webster et al. 2004). The authors reported no differences in relative densities of major bacterial lineages between biofilms that induced settlement and those that did not, and suggested metamorphic cues may be associated with particular bacteria species (Webster et al. 2004). Similarly, T-RFLP analysis of biofilm bacteria in this study revealed community-level differences among microbial films based on conditioning periods, tile surfaces and tile orientations. Further, distinct biofilm communities were recovered from tiles that induced settlement compared to those that did not. These results further highlight the complex nature of larvae-bacteria interactions and suggest multiple sensory cues from biofilm communities affect settlement choices by coral larvae.

Determining the environmental cues that dictate coral larvae settlement is essential to understanding how reefs will respond to and recover from reef degradation and is crucial for successful reef restoration programs. Loss of critical settlement cues from reef biota will result in continued, precipitous ecosystem declines by reducing coral recruitment at impacted sites. Identification of settlement cues may offer insight into preservation of biotic components that enhance reef recovery and aid restoration efforts, by providing a stock of metamorphic cues to enhance larval settlement under artificial conditions and the production of juvenile corals for transplantation to degraded reefs. The roles of some reef organisms (e.g., CCA) have been commonly targeted; however, other key organisms (e.g., bacteria) require further investigation. Additional studies targeting the role of coral reef microbial communities in larval settlement induction are required to fully elucidate the cues that attract new recruits and thus sustain reef ecosystems.

Multivariate responses of the coral reef fish community to artificial structures and coral transplants

S.C.A. Ferse

Center for Tropical Marine Ecology (ZMT) Bremen, Fahrenheitstr. 6, 28359 Bremen, Germany

Abstract. The effects of artificial structures and coral transplants on fish abundance, number of species, and community composition were examined during a two-year study at three locations in North Sulawesi, Indonesia. Three experimental treatments (10 x 10 m rubble plots (a.) left untreated, (b.) covered with concrete structures, and (c.) covered with a combination of structures and coral fragments) were monitored using monthly underwater visual censuses. An additional census of adjacent plots in the ambient reef served as comparison with the natural reef fish community. The effect of treatments differed between experimental sites. At the site with the lowest coral cover and structural complexity in the ambient reef, fish community responses were most marked, with an 8-fold increase in fish abundance in the Structures + Corals treatment compared to the untreated rubble plot. At the other two sites, abundance and number of species in the experimental treatments did not surpass that of the natural plots. At all locations, multivariate dispersion of the fish community samples decreased with increasing complexity of the experimental plots. The results underline the importance of reef context in the selection of appropriate restoration measures and show that results may differ depending on condition of the ambient reef.

Key words: coral transplantation, artificial reefs, Indonesia, fish community, restoration

Introduction

Coral reefs are complex, heterogeneous marine habitats mainly composed of biogenic carbonate structures that are deposited by hermatypic scleractinian corals and host numerous associated species of animals and plants (Vaughan 1919, Wells 1957). Fishes are among the most conspicuous reef dwellers. A wide range of fish species depend on live corals, e.g. for food or shelter (Patton 1976, Choat and Bellwood 1991, Cole et al. 2008). Fish abundance and species diversity are positively correlated with habitat complexity and amount of live coral cover (Risk 1972, Carpenter et al. 1982, Bell and Galzin 1984, Sano et al. 1984, Gratwicke and Speight 2005).

In response to the ongoing degradation of coral reefs world wide, the discipline of coral reef restoration has become increasingly established over the past two decades, although it remains largely in its infancy compared to the restoration of other ecosystems (Precht 2006, Edwards and Gomez 2007). Clark (2002) has cautioned that 'reef restoration is largely limited by incomplete knowledge on the ecosystem processes.'

Techniques frequently employed in coral reef restoration include the use of artificial reefs and transplantation of live corals (Jaap 2000, Clark 2002, Zimmer 2006), the latter currently being the most frequently used tool in active coral reef restoration (Edwards and Gomez 2007). However, despite the numerous studies on the link between live coral substrate and reef fishes, few workers have addressed the effects of coral transplantation on the reef fish community (Pamintuan et al. 1994, Cabaitan et al. 2008).

In this study, the effects of artificial structures alone and in combination with coral transplants on fish abundance and community composition were examined to gain a better understanding of the ecosystem processes pertaining to reef restoration.

Material and Methods

The present study was conducted at three locations in North Sulawesi, Indonesia (Fig. 1), between May 2005 and July 2007. The Gangga site was in the shallow upper reef slope in front of a dive resort, with low fishing pressure in the immediate vicinity of the experimental treatments, while the other two sites were at deeper sections of the reef slope (Table 1) and lay within the borders of Bunaken National Marine Park. At each site, three 10 x 10 m rubble plots were marked and cleared of remaining coral colonies and rocks, so that a flat rubble area remained. Plots lay at similar depths and were located between 5 and 20 m apart. At each site, the plots were randomly assigned to three treatments. Control plots (**C**) remained as empty rubble fields. In the other two treatments, the substrate was covered with 100 bamboo boards.

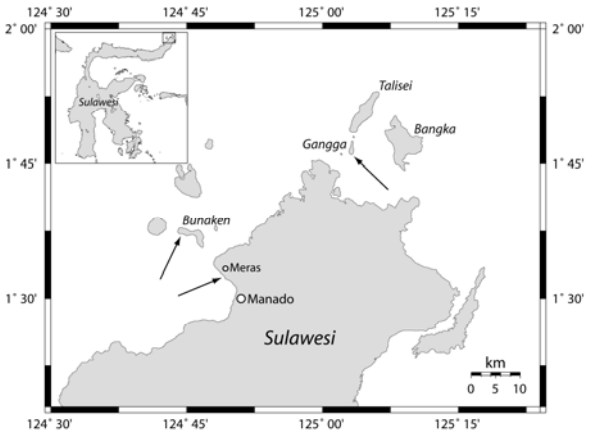

Figure 1: Map of northern Sulawesi, showing the three experimental sites. The location of the study area within Sulawesi is indicated on the inset map.

Artificial structures consisting of 5 concrete blocks each were then constructed on every second board in a chessboard pattern. In the Structures treatment (**S**), the remaining squares remained empty. In the Structures + Corals treatment (**S+C**), coral fragments were transplanted onto the empty bamboo boards between the structures (Fig. 2).

At each site, up to 2000 fragments of one species of branching *Acropora* were transplanted (Table 1). Species were selected based on abundance in the ambient reef. Each transplanted species occurred in large thickets in the vicinity of the recipient site. Additionally, fragments of *Pocillopora verrucosa* were transplanted at Gangga and Meras (Table 1). The fragments were distributed evenly among the boards and arranged at random on each board. A detailed description of the transplantation procedure is given by Ferse (2008).

Table 1: Depth of experimental plots, monitoring time frame and coral species transplanted for each site.

site	depth	monitoring	fragments transplanted*
Gangga	4-9 m	09.2005 – 05.2007	*Acropora yongei*: *n* = 1885 *Pocillopora verrucosa*: *n* = 475
Meras	12-20m	02.2006 – 06.2007	*Acropora formosa*: *n* = 1677 *Pocillopora verrucosa*: *n* = 378
Bunaken	12-19m	03.2006 – 05. 2007	*Acropora brueggemanni*: *n* = 1749

**n* = amount of surviving fragments at the time of the first visual census

A visual census of the fish community above the plots was conducted once per month, using three replicate counts carried out within the same day between 9:00 and 17:00 h. A SCUBA diver swam across each plot in four adjacent transects of 2.5 m width and 10 m length, counting and identifying all fishes present to a height of about 2.5 m above the substrate. Cryptic and pelagic species were excluded from the census. At the beginning of each count, horizontal visibility was estimated.

To compare the fish communities in the experimental plots with that of the ambient reef, per site two 10 x 10 m plots with substrate cover representative of the surrounding reef were marked in the vicinity of the experimental plots at similar depths, and a one-time census of the fish community with three replicate counts was carried out. Substrate composition in the natural reef plots, and detailed descriptions of the ambient reefs, are reported by Ferse (2008).

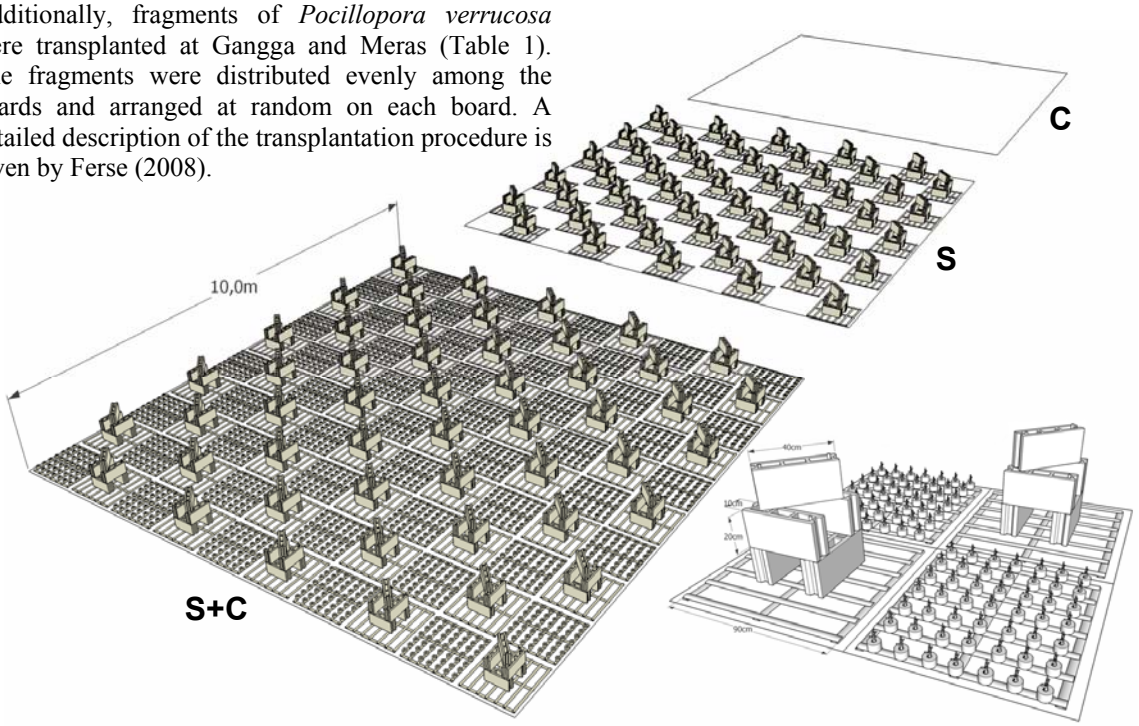

Figure 2: Sketch of the experimental set-up. In one treatment, artificial structures were interspersed with coral transplants (**S+C**, front), in a second one, only concrete structures were deployed (**S**, middle), and a third treatment consisted of a cleared coral rubble plot (**C**, back). A detailed drawing of the artificial structures and bamboo boards with attached coral transplants in shown on the lower right.

The effects of treatment on fish abundance and species diversity were assessed using a full-factorial general linear model, with time in days as independent variable and number of individuals and species as dependent variables. Underwater visibility was included as independent co-variable. Abundance data were square-root transformed to achieve normal distribution. Data from the natural reef plots were compared to data from the experimental plots taken at similar times using a one-way ANOVA. Where significant treatment effects were detected, a Tukey HSD post-hoc test at $\alpha = 0.05$ was performed to assess how treatments differed from each other. All univariate data analysis was carried out using JMP 7.0 (SAS Institute 2007).

For multivariate analysis of the fish community data, the program PRIMER 5.2.9 (Clarke and Gorley 2001) was used. Fish abundance data were fourth-root transformed and similarity of the samples was assessed using a zero-adjusted form of the Bray-Curtis coefficient (Clarke et al. 2006). To assess effects of treatments and sites on differences in the fish community composition, a crossed two-way multivariate analysis of similarities (ANOSIM) was used, and the relative multivariate dispersion of the community in the three treatments was analyzed for each site using the MVDISP routine.

Results

At all three sites, fish abundance increased markedly in the Structures + Corals treatment, while the increase in the Control plots was only slight (Fig. 3). The highest increase in abundance occurred at the shallow site (Gangga), where the number of individuals in the presence of coral transplants had increased almost 8-fold by the end of the experiment compared to the Control treatment. The linear model detected significant treatment effects (Table 2), and the post-hoc test confirmed significant differences between all three treatments.

Table 2: Results of the general linear model testing for effects of treatment, time and visibility on fish abundance at the three sites.

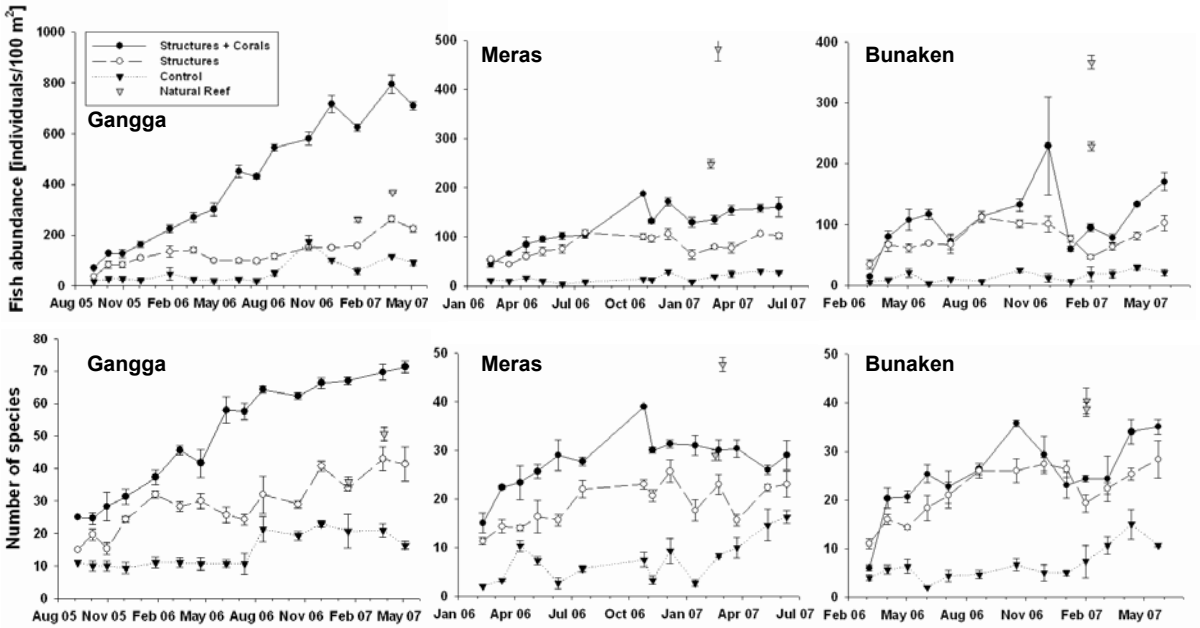

Figure 3: Fish abundance (above) and number of species (below) during consecutive censuses at the three locations (mean ± SE). The values observed during a comparative one-time census in two natural reef plots at each location are indicated by the gray triangles.

Fish abundance in the natural reef plots at Gangga was significantly lower than in the Structures + Corals treatment, but significantly higher than in the other two treatments (ANOVA, $F = 161.0741$, $p < 0.0001$, $df = 3,8$ and $F = 379.0192$, $p < 0.0001$, $df = 3,8$ for January 2007 and March 2007, respectively).

At the two deeper sites as well, the highest numbers of fishes occurred in the plots containing coral transplants. However, overall increases in abundance were less pronounced, and differences between the Structures and Structures + Corals treatments were not as marked as at Gangga (Fig. 3). Yet, the post-hoc test confirmed significant differences between all three treatments at both sites. Abundances in the natural reef plots were significantly higher than they were in the experimental plots at the time the ambient reef census was conducted (ANOVA, $F = 362.9089$, $p < 0.0001$, $df = 4,10$ and $F = 97.5778$, $p < 0.0001$, $df = 4,10$ for Meras and Bunaken, respectively).

The number of species followed similar trends as fish abundance at all sites. With few exceptions, species were most numerous in the presence of coral transplants, and the highest number of species was observed at Gangga (Fig. 3).

Table 3: Results of the general linear model testing for effects of treatment, time and visibility on number of species at the three sites.

Test	Factor	*df*	*F*	*p*
Gangga				
ANOVA	Model ($R^2 = 0.9272$)	11,117	135.65	<0.0001
Effect Test	Treatment	2	484.07	<0.0001
	Time	1	312.61	<0.0001
	Visibility	1	1.48	n.s.
	Treatment*Time	2	47.53	<0.0001
	Visibility*Time	1	0.83	n.s.
	Visibility*Treatm.	2	2.66	n.s.
	Vis.*Time*Treatm.	2	3.16	0.0461
Meras				
ANOVA	Model ($R^2 = 0.8724$)	11,110	68.38	<0.0001
Effect Test	Treatment	2	298.72	<0.0001
	Time	1	29.65	<0.0001
	Visibility	1	29.01	<0.0001
	Treatment*Time	2	0.36	n.s.
	Visibility*Time	1	4.15	0.0440
	Visibility*Treatm.	2	0.38	n.s.
	Vis.*Time*Treatm.	2	10.40	<0.0001
Bunaken				
ANOVA	Model ($R^2 = 0.7960$)	11,105	37.26	<0.0001
Effect Test	Treatment	2	141.82	<0.0001
	Time	1	54.55	<0.0001
	Visibility	1	4.91	0.0288
	Treatment*Time	2	2.23	n.s.
	Visibility*Time	1	0.23	n.s.
	Visibility*Treatm.	2	2.06	n.s.
	Vis.*Time*Treatm.	2	0.10	n.s.

Significant treatment effects were detected at all sites (Table 3), and post-hoc tests confirmed significant differences between the numbers of species in all treatments at each location. At Gangga, the amount of species in the natural reef plots did not differ significantly from that in the Structures treatment but was significantly different from the number of species in the other two treatments (ANOVA, $F = 48.9081$, $p < 0.0001$, $df = 3,8$ and $F = 59.5524$, $p < 0.0001$, $df = 3,8$ for January 2007 and March 2007, respectively).

Species number in one of the natural reef plots at Meras did not differ significantly from the number of species in the Structures + Corals plot. In the second natural plot at Meras, and in both natural plots at Bunaken, the amount of species observed was significantly higher than that found in the experimental plots at the same time (ANOVA, $F = 82.1000$, $p < 0.0001$, $df = 4,10$ and $F = 40.4127$, $p < 0.0001$, $df = 4,10$ for Meras and Bunaken, respectively).

Multivariate analysis of the fish community data revealed significant effects of treatment as well as location on community composition (Table 4).

Table 4: Results of a crossed two-way ANOSIM for effects of treatment and location using all experimental fish census samples.

Test	Factor	Test pairs	ρ
global	Treatment		0.643*
pairwise		Control, S + C	0.802*
		Control, Structures	0.751*
		S + C, Structures	0.564*
global	Location		0.830*
pairwise		Gangga, Meras	0.933*
		Gangga, Bunaken	0.891*
		Meras, Bunaken	0.664*

*significant at $p = 0.001$

As indicated by a multi-dimensional scaling plot of the averaged fish community data from all experimental plots (Fig. 4), the relative multivariate dispersion was highest in the Control treatment (MVDISP, relative dispersion 1.247, 1.688 and 1.489 at Gangga, Meras and Bunaken, respectively), while data from the Structures + Corals treatment were least dispersed (MVDISP, relative dispersion 0.734, 0.672 and 0.765 at Gangga, Meras and Bunaken, respectively).

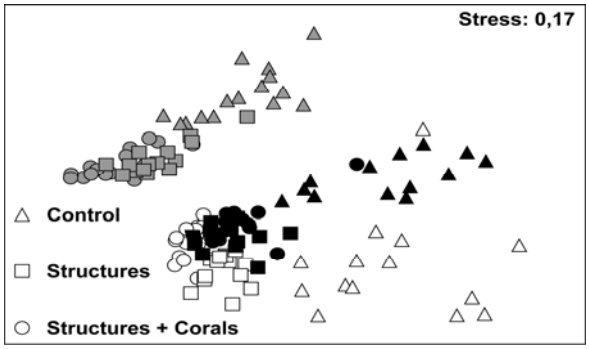

Figure 4: Non-metric Multi Dimensional Scaling (MDS) based on Bray-Curtis similarity of the average fish community data from all censuses of the experimental plots. **Gray:** Gangga, **White:** Meras, **Black:** Bunaken.

Discussion

Besides serving as food for corallivores, coral colonies can provide protection or additional habitat for fishes (e.g., Bell and Galzin 1984, Sano et al. 1984, Friedlander et al. 2003). As such, the observed positive effect of transplantation on fish abundance is not unexpected. However, fish community responses differed between the experimental sites. The most marked responses were observed at Gangga, where hard coral coverage in the ambient reef plots was less than 5 % (Ferse 2008). At Meras and Bunaken, where hard corals cover was between 13 and 29 % and the ambient reef was more heterogeneous than at Gangga, the effects of structures and coral transplants were less striking, and the values in the experimental plots remained below those in the ambient reef plots.

In previous studies, artificial reefs placed in areas of low complexity and little live coral cover have resulted in very high fish abundance and biomass (Randall 1963, Edwards and Clark 1993), while structures placed in biologically rich and structurally complex environments had values lower than the natural reef (Burchmore et al. 1985). Similarly, while the provision of structures and transplants was able to exert a significant impact on the fish community at Gangga, it appears that the experimental plots at the other two sites were not as attractive to fishes as the ambient reef area. This underlines that condition of the ambient reef should be a major consideration in the selection of appropriate restoration methods.

As indicated by a decrease in the relative multivariate dispersion of the community samples, structures and coral transplants aided in the establishment of a distinct fish community at all sites. Higher multivariate dispersion has been found in fish communities over degraded reef areas compared to healthy reef flats (Dawson Shepherd et al. 1992), and an analysis of relative dispersion may thus be an additional tool in judging the effects of restoration efforts.

Acknowledgements

Sincere thanks are due to Froggies Divers and Gangga Island Resort and Spa for logistical support, and to S. Romatzki for help in the field. A. Kunzmann and two anonymous reviewers provided helpful comments on the manuscript. This study was financially supported by a doctoral scholarship from the German National Academic Foundation.

Abstract. Giant barrel sponges, *Xestospongia muta*, are abundant and important components of the southeast Florida reef system, and are frequently injured from anthropogenic and natural disturbances. There is limited information on the capacity of *X. muta* to recover from injury and on methods to reattach *X. muta* fragments. In late 2002, hundreds of barrel sponges offshore southeast Florida (Broward County) were accidentally injured during an authorized dredging operation. In early 2003, two to three months post-injury, 93% of 656 assessed injured sponges appeared to be recovering. In 2006, three years post-injury, nearly 90% of 114 monitored sponges continued to show signs of recovery. Growth rates were estimated by measuring sponge height above visual injury scars and ranged from 0.7 cm yr^{-1} to 6.0 cm yr^{-1}. Information on the artificially reattached fragments is limited but did show that *X. muta* fragments can reattach. This study provides evidence that *X. muta* in southeast Florida can naturally recover. Details on sponge size class associated recovery processes and growth were not collected due to event associated legal issues limiting the study. Studies to determine detailed growth rates and recovery success for different injury and restoration scenarios will further facilitate restoration decision making by resource managers.

Key Words: Barrel sponge, *Xestospongia muta*, recovery, reattachment, restoration

Introduction

The giant barrel sponge, *Xestospongia muta*, is an abundant, large, and important component of the southeast Florida reef system. Sponges are potentially very long-lived (McMurray et al. 2008) and have important ecological roles in reef ecosystems including filtering large volumes of water, contributing to habitat complexity, and increasing diversity with numerous associated infauna and microbial communities (Diaz and Rutzler 2001; Hentschel et al. 2006). Offshore Florida, *X. muta* colonies are often injured by marine construction activities (e.g. dredge projects), ship grounding and vessel anchoring events, line fishing, and storms (Schmahl 1999; Chiappone et al. 2002; Collier et al. 2007). Although *X. muta* has been shown to successfully heal small scale wounds, such as those caused by fish predation, few studies have focused on monitoring recovery from more severe injuries (Schmahl 1999; Walters and Pawlik 2005). There is also scant literature on the ability of *X. muta* fragments or dislodged barrels to reattach to the substrate. The limited availability of information on sponge fragment attachment success and natural recovery of severely injured sponges constrains the ability of resource managers to determine primary and compensatory restoration actions following injuries to *X. muta* populations (Jaap 2000; Collier et al. 2007).

In November 2002, during an inlet channel improvement project, steel tow cables were accidentally dragged over middle and outer reef areas offshore Broward County, southeast Florida. Damage to coral reef communities included the complete dislodgment of and various degrees of injury to hundreds of *X. muta* sponges. Injury assessment and primary restoration activities included the identification of injured barrel sponges and the reattachment of sheared sponge fragments. A monitoring effort was designed and included a representative sample of tagged injured sponges and transplanted fragments. Although legal issues (outside the scope of this paper) limited the monitoring effort, this study provides important information on the ability of *X. muta* to recover following severe injury and fragment attachment success.

Materials and Methods

Initial recovery

From December 2002 to February 2003, one to four months after the injury event, reef injury areas were assessed and mapped. As directed by the resource trustees (state of Florida), two types of additional assessments (transect and total-count) were conducted

to document initial *X. muta* recovery within a portion of the injury areas. Within seven mapped injury areas a total area of 900m² was assessed using 24, 0.75m x 50m, non-fixed, belt-quadrat transects. Four transects were completed within each of five of these injury areas and two transects were completed within two injury areas, and all transect locations were placed such that their entire length were within the mapped injury areas.

Within six total-count injury areas, which had a total injured area of 7,272m², all barrel sponges were counted and classified. For both of these rapid assessments, the trustees only requested information on the number of recovering sponges. No quantitative information on sponge sizes was collected. Injured sponges were classified as: *sheared*, with the entire barrel removed (Fig. 1), or *notched*, with only a portion of the barrel removed and most of the sponge remaining intact (Fig. 2). The condition of each sponge was also noted as recovering or not recovering. A recovering sponge was defined by the absence of necrotic tissue, darkening of the internal tissues exposed by the injury, and/or visible new growth.

Figure 1: Base of a sheared barrel sponge with a completely removed barrel and recently exposed internal tissues (white).

Fragment attachment

Also between December 2002 and February 2003, 401 *X. muta* fragments (sheared barrels) were collected and artificially attached to the substrate within the injury areas. Two methods were employed. In both methods, prior to attaching fragments, loose sediments, algae, and other material were removed to promote sponge growth onto the substrate. For the first method (210 of the 401 fragments) two lengths of stainless steel wire were crossed and draped over the fragment. The wire was pulled tight pressing the fragment against the substrate. The ends of the wire were secured to the substrate with cut nails. The second method (191 of the 401 fragments) utilized Portland cement to attach a portion of the fragment directly to the substrate. At the time of reattachment no data was collected on fragment size.

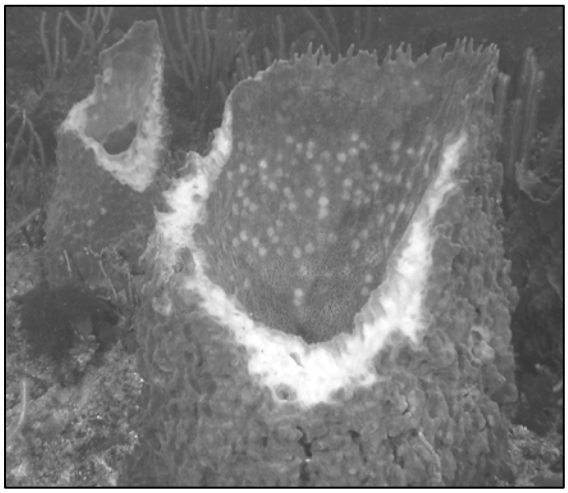

Figure 2: Two sponges with notched barrels and recently exposed internal tissues (white).

Long-term recovery

In March 2003, 11 monitoring zones were established to document long-term *X. muta* recovery within the injury areas. Four (zones 7, 9, 10, and 11) monitoring zones included injury areas within which the initial recovery assessments were completed. Zones were marked by a permanent center pin and included area around the pin defined by a radius of approximately 15m. Artificially reattached fragments and injured sponges within each zone were mapped and tagged. All sponges were alive and showed signs of recovery at the time of tagging. In December 2006 and January 2007, the 11 monitoring zones were visited and the tagged barrel sponges were assessed. For injured sponges and reattached fragments, condition was noted as recovering (alive) or missing (tag found but sponge missing). For the injured recovering sponges only, sponge height was recorded and new growth was estimated (when possible) by measuring (nearest cm) the height of tissue above the injury 'scar' (Fig. 3). Growth rates were estimated by dividing the measured new growth by the number of months between the injury and the time of measurement. This monthly growth rate was then multiplied by 12 for yearly growth. Growth had to be estimated due to the legal issues which stopped the project prior to collecting initial quantitative data in 2003 on sponge sizes. These same legal issues did not permit visits to the zones prior to the late 2006/early 2007 monitoring event.

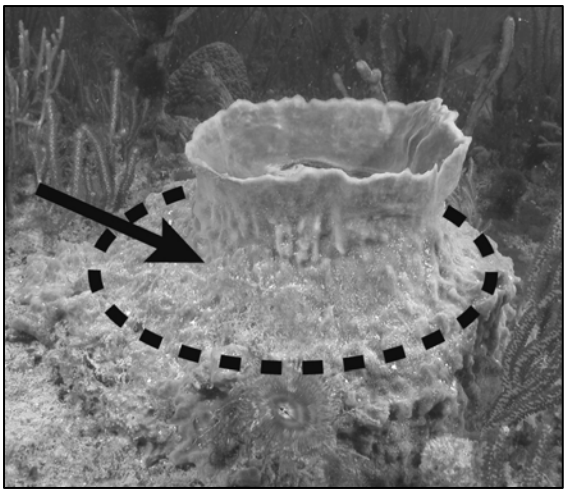

Figure 3: Injured barrel sponge in 2007 with the area of new growth (arrow) above a visible injury scar (dotted line).

Results

Initial recovery

Within the 24 transects 180 injured *X. muta* were identified with 13 classified as notched and 167 as sheared. Of these 180 sponges, 100% of the notched and 92% of the sheared (154 sponges) showed signs of recovery for a total initial recovery of 93% (167 sponges) (Table 1).

A total of 476 injured *X. muta* were identified within the six total-count injury areas. Forty-eight sponges were classified as notched and 428 as sheared. Forty-five notched sponges (95%) and 400 sheared sponges (93%) were recovering for a total recovery of 93% (Table 1).

Fragment attachment

Within the 11 monitoring zones, 26 reattached fragments were present and tagged. Six fragments were secured with cement and 20 with wire. During the 2006/2007 monitoring event, only five fragments (all wire) remained alive and had attached to the substrate (Fig. 4). The monitoring tags of the remaining 21 fragments (six secured with cement and 15 with wire) were found but the fragments were missing.

Figure 4: Artificially reattached barrel sponge fragment in 2007. Note the wire used to secure the fragment and the change in fragment growth orientation from vertical to horizontal.

Table 1: Initial recovery summary data for the seven transect and the six total-count (T-C) injury areas. Sponge totals for each assessment type and combined totals for both types are indicated (T = total sponges, N = notched sponges, S = sheared sponges).

Long-term recovery

In 2003 within the 11 monitoring zones, 114 injured *X. muta* were tagged (Table 2). In late 2006/early 2007, 102 (90%) were found alive (recovering). Of the 11 monitoring zones, five had 100% recovery, and only one zone (zone 3) had less than 80% recovery (71.4%) (Table 2). Estimated new growth rates (recovery) of 101 surviving colonies ranged from 0.7 cm yr^{-1} to 6.0 cm yr^{-1}, with a mean of 2.78 cm yr^{-1} (± 0.11 SEM). It was noted during the late 2006/early 2007 monitoring event that many of the recovering sponges had multiple barrels. Notes were recorded for 92 recovering sponges, and 59 were identified with one barrel, 14 had two barrels, and 19 had three or more barrels (Fig. 5).

Table 2: Number of sponges tagged within each monitoring zone (MZ) in 2003, and the number of sponges recovering, missing, and percent recovery from the late 2006/early 2007 monitoring event.

Discussion

The high latitude southeast Florida reef system is offshore a heavily populated coast and is therefore subject to multiple natural and anthropogenic stressors. Strong storm events, unauthorized injury events such as ship groundings, and authorized coastal construction projects potentially impact reef resources. There have been few efforts with almost no information recorded on restoring sponge populations and documenting recovery. Generally, reef restoration activities and recovery monitoring efforts concentrate on stony corals. Sponges are a dominant component of the southeast Florida reef system contributing greatly to benthic cover and density (Gilliam et al. 2007, 2008). Therefore, information on the capacity of sponges to recover and techniques to restore sponge populations following injury are needed.

Even though legal issues limited the information that may have been available, this study provides an example of the capacity of the giant barrel sponge, *Xestospongia muta*, to recover from severe injuries. Observed recovery of all sponges (notched and sheared) within several months of the injury event was over 93% and after four years was nearly 90% (Tables 1 - 2).

These recovery rates are higher, yet comparable to, those documented for *X. muta* offshore the Florida Keys, in which 30 out of 37 (81%) *X. muta* were considered recovered 13 months after suffering injury from a ship grounding (Schmahl 1999).

Although the growth rates of the recovering sponges in this study were estimates only and were highly variable, they fell within the range of other documented upward linear growth rates in the Florida Keys (Schmahl 1999, McMurray et al. 2008). Interestingly, mean injured sponge growth rates were higher in Broward County (2.78 cm y^{-1}) than recovering sponge growth rates in the Florida Keys (1.94 cm yr^{-1}, Schmahl 1999). Regardless of this difference, these elevated growth rates provide some evidence for the supposition that recovering sponges have higher-than-normal growth rates (1.85 ± 1.10 cm yr^{-1}, McMurray et al. [2008]).

Two methods were used to reattach sponge fragments. Although 401 total fragments were reattached, at the time the monitoring zones were established only 26 fragments were identified within the 11 zones. The exact fate of the remaining 375 fragments is unknown. They were either lost prior to zone establishment or were present within the injury areas but outside of the established zones. None of the six monitored fragments secured with cement were present in late 2006/early 2007. Observations immediately after cementing showed that the fragment was initially held to the substrate. It is likely

that due to the mortality of sponge tissue in contact with the cement, the fragment was not held in contact with the substrate for a time period necessary for the sponge tissue to grow. Five of 20 monitored fragments attached by the wire were found attached to the substrate in late 2006/early 2007. For those five the wire was able to hold the fragments tight against the substrate long enough for sponge tissue to grow. Growth was also observed over the wire. This limited data suggests that if *X. muta* fragments can be secured tightly against the reef substrate for a sufficient length of time, they are capable of forming a new attachment and will continue to grow. Because of the small sample size we can not conclude the attachment of *X. muta* fragments using wire is the best method and other methods should be evaluated. For some of the fragments, wave and surge conditions created a "sawing" effect with the wire, where it sliced downward into sponge tissue. Subsequently, the fragment was unable to remain in contact with the substrate, thereby preventing the stability required for reattachment. It is also interesting to note that several fragments that were not placed in their original growth orientation were still able to successfully reattach. These fragments were essentially "half barrels" and the portion of the barrel top, which was initially vertical, was attached horizontally (Fig. 4).

This study was interrupted for a period of three years due to legal issues associated with the injury event. This gap resulted in a significant amount of data loss especially in terms of sponge size class associated rates of new growth and causes of mortality. Nonetheless, this limited study does provide important information on the recovery of *X. muta* offshore southeast Florida, USA and supports the necessity for comprehensive, long-term monitoring efforts. Current research includes a controlled study to further explore *X. muta* recovery, growth, causes of mortality, and effectiveness of reattachment methods.

Abstract. Studies have shown that marine biofilms play an important role in coral larval settlement. Biofilms are formed when substrata are immersed in seawater over a period of time in a process known as conditioning. This study investigated the settlement of *Pocillopora damicornis* larvae on concrete tiles which had been conditioned in running seawater for one, two, four, six and eight weeks, with unconditioned tiles used as controls. Results showed that larval settlement appeared to be higher on unconditioned tiles. Two-way ANOVA indicated no significant differences in larval settlement densities in treatments and controls, but significant differences in the choice of settlement surfaces preferred. Larvae preferred to settle on the sides of the tiles, compared to the top and bottom surfaces. Regression analysis conducted on the weight of sediment accumulated and the density of settled larvae indicated a negative and significant correlation between the two variables. Sediment accumulation on biofilm layers growing on underwater substrata likely affects the suitability of these surfaces for larval settlement. This factor must be taken into account when designing artificial surfaces to enhance coral larval settlement for reef rehabilitation.

Key words: *Pocillopora damicornis*; larval settlement; biofilm; sediment

Introduction

The life history of sessile marine invertebrates is affected by the behaviour of larvae during the planktonic and settlement phases as well as by post-settlement mortality (Keough and Downes 1982). Various environmental, chemical and biological cues influence larval settlement. Crustose coralline algae (CCA), skeleton and coral rubble have been used to provide the necessary cues to induce settlement of corals (Morse et al. 1988; Heyward and Negri 1999; Webster et al. 2004). Biological cues such as marine biofilms also play an important role in coral larval settlement.

Marine biofilm formation occurs on any substrate immersed in natural seawater (Wimpenny 1996). A layer of organic molecules is immediately formed on the clean substrate surface when placed in seawater. During conditioning, marine bacteria, diatoms and algal spores grow on the surface, and sediment also accumulates on the surface to form a complex biofilm layer (Kirchman et al. 1982; Mitchell and Maki 1988; Gilmour 1999). The formation of marine biofilms is a dynamic colonization process that may change over time (Webster et al. 2004; Shikuma and Hadfield 2006). The settlement of larvae is affected by the length of time a natural marine biofilm has developed on a substrate. The layer of marine biofilm potentially affects the recruitment of larval benthic invertebrates (Characklis and Cooksy 1983; Webster et al. 2004). An increase in the duration of substrate conditioning has been reported to significantly increase the rate of coral larval metamorphosis (Webster et al. 2004).

The absence of sediment on substrate is essential for coral settlement (Harrington et al. 2004). However, coral reefs are increasingly exposed to natural and anthropogenic disturbances in the past few decades (Rogers 1979; Wilkinson 1998). These disturbances include increased nutrient levels, sedimentation, pollution and eutrophication in the marine environment, and have been reported to promote succession changes in reef communities (Birkeland 1987; Belliveau and Paul 2002; Fabricius 2005). A study showed that suspended sediment, and the accumulation of sediment on the upper surface of settlement substrate negatively affected larval settlement of *Acropora digitifera* (Gilmour 1999).

Singapore is a highly urbanised country, and has a steadily expanding economy. The marine environment has contributed to Singapore's success as one of the world's busiest ports and one of the

largest oil-refining centres (Chou and Goh 1998). However, the presence of numerous human activities along the coastline, such as shipyards and coastal development (Chua and Chou 1992), has resulted in degradation of the reefs. High sedimentation (45 mg cm^{-1} day^{-1}) has been recorded in Singapore waters (Low and Chou 1994). Generally, coral reefs do not extend beyond the 6 m depth due to high water turbidity and sediment load (Chou and Tun 2005).

The objective of the present study was to investigate the effect of conditioning artificial tiles in seawater, on the settlement of *Pocillopora damicornis* larvae. The ease of collection and maintenance of *P. damicornis* larvae, in addition to the regular planulating cycle of the adults make this species of coral a suitable test organism for the present study. This study also examined the accumulation of particulate matter on biofilm layers formed on conditioned tiles, and their effects on larval settlement.

Materials and Methods

Preparation of settlement substrates and larval collection

Cement tiles (of dimensions: 10x10x1cm) containing 10% of coral rubble (10% CR) were used as settlement substrates. Tiles (placed horizontally) were conditioned in flow-through seawater systems in indoor aquaria. Tiles were conditioned for 1, 2, 4, 6 and 8 weeks, making up five treatments. All experiments were conducted at the Tropical Marine Science Institute under aquarium conditions. Adult colonies of *P. damicornis* were collected from Singapore reefs and maintained in aquaria for planulation. Planulation occurred after the new moon, and *P. damicornis* larvae were collected in overflow collectors.

Effect of duration of tile conditioning on coral larval settlement

The larval settlement experiments were carried out in March 2007. A single experimental tile was placed in a 2 L polyethylene tank containing UV-treated seawater and 20 larvae were introduced into each treatment tank. Four replicate tanks were prepared for each treatment and Controls, which comprised clean, unconditioned tiles. The numbers of coral larvae which had settled on each tile were enumerated after a 10-day exposure experimental period.

Determination of particulate matter

In a larval settlement experiment repeated in February 2008, a determination was also made of the amount of particulate matter that had settled on the experimental tiles.

After the end of the exposure experiment and enumeration of settled larvae, particulate matter that may have collected from the top surfaces of settlement tiles were washed off with gentle agitation in clean filtered UV-treated seawater. Particulate matter removed from individual tiles was filtered in the laboratory onto Whatman GF/C filter paper. The filter paper was then dried in an oven at 65ºC over 24h, and the dry weight of the filtered particulate matter obtained thereafter.

Statistical analysis

A log (x+1) transformation was applied to the data (density of settled larvae) before statistical treatment. Two-way Analysis of Variance (ANOVA) with Tukey's post-hoc test were conducted on the density of settled coral larvae to determine if significant differences in settlement existed in the different treatments (different tile conditioning durations), and if coral larvae had a preference for a tile surface (top, sides, or bottom). Linear regression analysis was performed on the dry weights of particulate matter and numbers of settled larvae to determine possible relationships.

Results

The 10% CR tiles conditioned in aquaria for periods from 1 to 8 weeks showed different degrees of biofilm formation (Fig. 1).

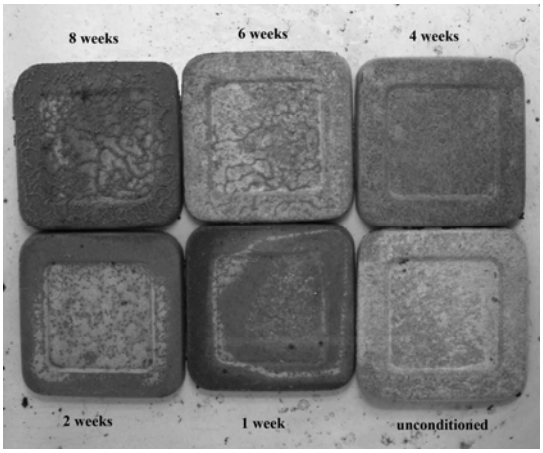

Figure 1: Surfaces of tiles conditioned for different periods of time in a running seawater system in indoor aquaria, showing different degrees of biofilm formation.

Two-way ANOVA on density of larval settlement data showed no significant interaction between the duration of tile conditioning and preferred settlement surfaces (top, sides, or bottom) on experimental tiles ($p > 0.05$; Table 1). Tukey's test revealed no significant differences in the mean settlement densities on tiles conditioned for different periods of

time ($p > 0.05$), but significant differences in settlement on different surfaces of the tiles ($p<0.05$, Table 1 and Fig. 2).

Table 1 Results of 2-way ANOVA on coral settlement density crossed with factors: duration of tile conditioning (0, 1, 2, 4, 6, and 8 weeks) and tile surfaces (top, sides or bottom), and results of Tukey's test. (* indicates significant treatment effects)

Factors	*df*	*F*	*p*
Duration of conditioning	5	1.923	>0.05
Tile surface	2	15.800	<0.05*
Duration × Surface	10	1.977	>0.05

The mean number of settled larvae showed a tendency to decrease with increasing periods of tile conditioning (Fig. 3). The highest settlement rate occurred on the clean, unconditioned tiles (Controls), and there was a gradual decrease in larval settlement on tiles conditioned for longer periods of time (Fig. 3). These results indicated that the larvae preferred to settle on clean, unconditioned 10% CR tiles.

The mean density of larvae that settled on the sides of the tiles were significantly greater than at the top surfaces of the tiles (Fig. 2).

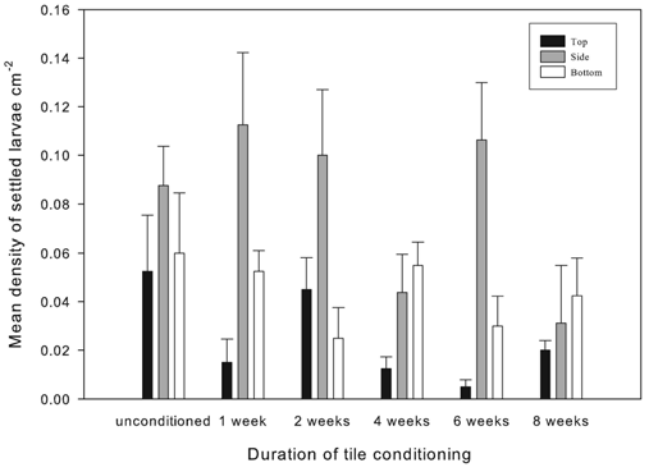

Figure 2: Mean density of settled *P. damicornis* larvae observed on different surfaces of tiles conditioned for different periods of time. (Means of 4 replicate aquaria; Error bars show standard error)

Regression analysis indicated a significant, negative relationship between the mean number of settled larvae and weight of particulate matter on experimental tiles ($r^2 = 0.512$, $p < 0.05$, $n = 24$; Fig. 4).

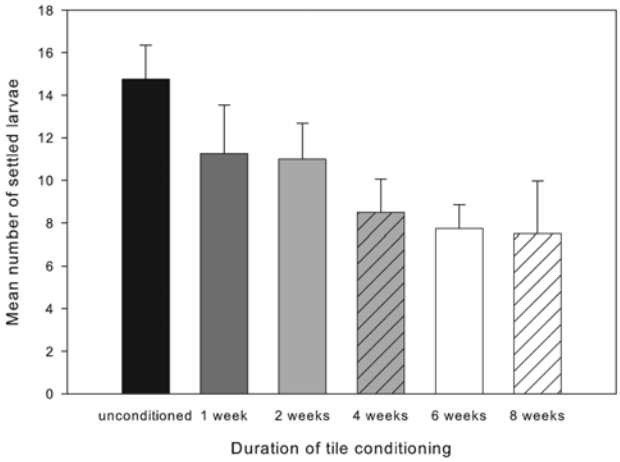

Figure 3: Mean number of settled *P. damicornis* larvae observed on 10% CR tiles conditioned for different lengths time over a 10-day experimental period in aquaria. (Means of 4 replicate aquaria; Error bars show standard error)

Discussion

P. damicornis larvae showed decreasing rates of settlement in relation to the duration of tile conditioning. In the experiment, larvae had a clear propensity to settle on clean tiles, suggesting that conditioning of 10% CR tiles was not necessarily a requirement for promoting larval settlement. A possible explanation of the results obtained may be that the longer duration of tile conditioning in a natural flow-through seawater tank also resulted in the accumulation of higher amounts of fine sediment on the top surfaces of the tiles.

In the present study, larvae seemed to have a marked preference for the sides (vertical surfaces) of the tiles for settlement. In a settlement orientation study of the corals, *Platygyra sinensis* and *Oxypora lacera*, larvae were significantly affected by physical and biological factors under natural conditions (Babcock and Mundy 1996). Settlement on vertical surfaces was also observed in an experiment which reported that tiles positioned between angles of 60° and 90° induced higher larval settlement (Carleton and Sammarco 1987).

Increasing sediment accumulation was observed on the top surfaces of tiles conditioned for longer periods of time in the study repeated in February 2008. The results also demonstrated that the presence of fine sediment decreased the effectiveness of potential suitable substrates for larval settlement of *P. damicornis* (Fig. 4). Sediment has been reported to inhibit the settlement of coral larvae (Hodgson 1990; Babcock and Davies 1991; Babcock and Mundy 1996). Larvae respond to negative chemical or physical cues due to the accumulation of sediment layers on the substrates (Hodgson 1990). Another

study demonstrated that suspended sediments and the accumulation of sediment on the upper surfaces significantly inhibited larval settlement of *Acropora digitifera* on CCA-covered substrates (Gilmour 1999).

It is likely that differences in microbial density and microbial community composition results from conditioning tiles for different durations of time. Few studies have focused on the role of the microbial biofilms on coral settlement. In tropical waters, the composition of marine biofilms fluctuate over time (Webster et al. 2004). Surfaces with different compositions, densities, ages and origins of biofilm attract different marine invertebrate larvae to settle (Parsons et al. 1993; Wieczorek and Todd 1998; Patel et al. 2003), and many larvae prefer to settle and metamorphose on multi-species biofilms (Kirchman et al. 1982; Patel et al. 2003). The community composition of the biofilm depends on the bacterial species which colonise the substrates. For example, *Pseudoalteromonas* bacteria isolated from CCA was able to induce larval settlement of *Acropora willisae* (Negri et al. 2001). Although the conditioned tiles may have developed a complex layer of microbial communities on their surfaces, this may have enhanced the accumulation of silt and sediment, rendering the surfaces unfavourable to the coral larvae. More studies are needed to investigate and to understand the role that microbial communities play in coral larval settlement.

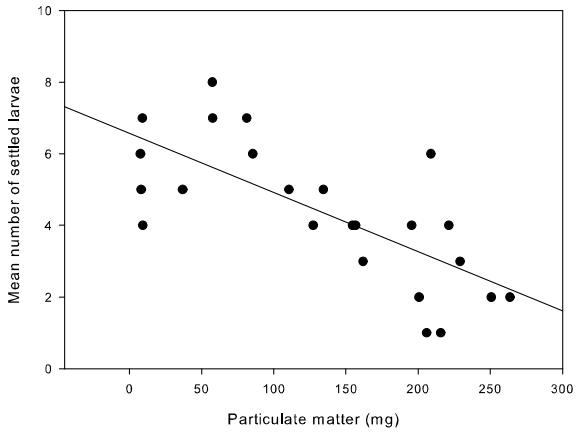

Figure 4: A negative relationship between mean number of settled larvae and the weight of particulate matter on conditioned tiles. The solid line through the data represents a least-squares regression.

Pocillopora damicornis is a brooder with a monthly planulation cycle. The larvae of coral species that are brooders tend to demonstrate more general responses to cues for metamorphosis and settlement (Baird and Morse 2004). It would be interesting to investigate the effects of substrate conditioning with sediment-stress on larvae from other species of corals which are broadcast spawners, to determine if similar responses are elicited.

In conclusion, increasing durations of substrate conditioning did not enhance larval settlement, possibly due to increasing accumulation of fine sediment on the substrates. Therefore, the characteristics and properties of substrates should be carefully considered in the selection of substrate surfaces to ensure high larval settlement. More research is necessary to investigate the physical and chemical properties of artificial substrates, the composition of biofilm/sediment layer found on biologically conditioned tiles, and species-specific preferences for coral larval settlement.

Coral recruitment and community development: the Broward County artificial reef compared to adjacent hardbottom areas, five years post-deployment

A.R. Hannes and L.S. Floyd

Coastal Planning & Engineering, Inc., 2481 NW Boca Raton Blvd., Boca Raton, FL 33431, USA

Abstract. Artificial reefs have been utilized as a tool for reef conservation, rehabilitation and mitigation. The success of artificial reefs is measured by their ability to mimic the natural hardbottom environments which they are intended to replace. Despite the numerous artificial reef studies, there are few comparative studies between artificial and natural reefs. This study examines recruitment and subsequent development of coral communities on an artificial reef, and compares them to adjacent natural hardbottom in Broward County, Florida, USA. We compare artificial to natural hardbottom coral communities by examining abundance, diversity and size class distribution over time. Scleractinian and octocoral abundance, diversity and average size on the artificial reef was nearly equal to those on the natural nearshore hardbottom five years post-deployment. This study presents the data from each of the seven monitoring events and discusses the variables contributing to coral recruitment and community composition on artificial reefs.

Key words: recruitment, artificial reefs, mitigation

Introduction

Coral reefs worldwide are in a state of decline and experiencing considerable degradation (Wilkinson 2000). Artificial reefs are frequently utilized as a means of rehabilitating and restoring degraded natural reefs (Bohnsack and Sutherland 1985; Seaman 2002), and in recent years artificial reefs have been deployed to prevent or mitigate for impacts resulting from anthropogenic damage (e.g., coastal development, ship groundings, pollution, etc.) (Spieler et al. 2001).

A majority of artificial reef studies have focused on the early colonization stages of benthic communities, while relatively few have included long-term monitoring to evaluate the development of artificial reef communities beyond the initial successional phases. In spite of the considerable attention paid to artificial reefs, there is also a scarcity of comparative studies between artificial and natural reef communities (Perkol-Finkel and Benayahu 2005). If we are to successfully utilize artificial reefs as tools for rehabilitation and restoration of degraded marine habitats, then more emphasis must be placed on evaluating the ability of benthic artificial reef communities to mimic those found on the natural reef (Perkol-Finkel and Benayahu 2007).

The current study presents results of five years of monitoring following the deployment of a limestone boulder artificial reef in Broward County, Florida, USA. In particular, the scleractinian and octocoral communities on the artificial reef are compared to those found on adjacent natural hardbottom substrate. Scleractinian and octocoral abundance, diversity and size class distribution are compared between the artificial and natural reef communities for each of seven monitoring events in order to evaluate the success of the artificial reef in resembling the natural community it was intended to replace.

Materials and Methods

Artificial and natural reef monitoring protocol

Construction of the Broward artificial reef was completed September 2003. The artificial reef was constructed as one layer of limestone boulders (1.2-1.8 m in maximum diameter) placed in the nearshore zone in approximately 4 to 6 meters mean water depths. Coral communities were evaluated using the Coastal Planning & Engineering, Inc. Benthic Environmental Assessment for Marginal Reefs (BEAMR) method (Lybolt and Baron 2006). A total of 54 30-meter long permanent transects were established on the artificial reef and the adjacent natural hardbottom (27 artificial transects, 27 natural transects). BEAMR was conducted along each transect using 12 replicate 1.0-m^2 quadrats (1.0 m x 1.0 m) spaced along the transect every 2.5 meters, starting at 0.0 m. Scleractinian coral colonies were identified to species level and octocoral colonies

were identified to genus level. Size was measured to the nearest cm. All natural and artificial transects were monitored 9-, 12-, 18-, 24-, and 36-months after artificial reef deployment. A subset of artificial reef transects was also sampled 48-months post-deployment. The artificial reef transects were all surveyed again at 60-months post-deployment.

Data analysis

Using PRIMER (v6) (Clarke and Gorley 2006), a Bray-Curtis similarity coefficient matrix was derived based on scleractinian and octocoral abundance per meter area of hardbottom for artificial and natural sites for each monitoring period. This similarity matrix was used to track the scleractinian and octocoral community changes at the artificial and natural habitats over time. Non-parametric multidimensional scaling (MDS) ordinations were created from the similarity matrices for both scleractinian and octocoral datasets. Simple agglomerative hierarchical clustering (Cluster) and similarity profiles (SIMPROF) were performed on both datasets to determine statistically significant differences in community structure over time.

Using PRIMER (v6) (Clarke and Gorley 2006), species richness (*S*), Shannon diversity index (*H'*), Simpson index (*1-λ'*), Pielou's evenness index (*J'*), and Margalef's index (*d*) were calculated for artificial and natural sites for scleractinian and octocoral communities over time.

Coral size class structures for artificial and natural sites were analyzed by calculating the scleractinian and octocoral size class abundance per meter area of hardbottom for each monitoring period. Size class profiles were compared to track changes in artificial and natural areas over time.

Results

Scleractinian community

Results from the MDS show that the scleractinian community at the natural hardbottom sites has remained stable over time, whereas, the scleractinian community on the artificial reef has gradually become more similar to the natural hardbottom community from 9-months to 60-months post-deployment (Fig. 1). Results of the SIMPROF suggest that the there have been three significant shifts in the scleractinian community on the artificial reef from 9-months to 60-months post-deployment, at which time the scleractinian community at the artificial reef has attained 70% similarity to the natural hardbottom community (Fig. 1).

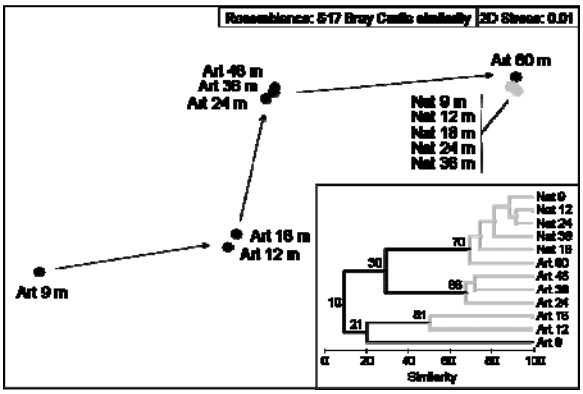

Figure 1: Two-dimensional MDS plot and corresponding SIMPROF dendrogram based on scleractinian abundance m^{-2} of hard substrate. Monitoring groups connected by grey lines cannot be significantly differentiated ($p \leq 0.05$).

Species richness at the natural sites remained between 11 and 14 species throughout monitoring (Table 1), whereas, species richness at the artificial reef climbed steadily throughout the duration of monitoring from 2 to 13. Diversity indices indicate that scleractinian diversity on the artificial reef increased steadily and by 60-months post-deployment, all four diversity indices surpass those of the natural reef (Table 1).

Table 1: Measures of scleractinian diversity on artificial reef and natural hardbottom.

	Scleractinians									
	Species Richness (S)		Shannon (H')		Simpson ($1-\lambda'$)		Pielou's (J')		Margalef's (d)	
Post-Deployment	Art	Nat	Art	Nat	Art	Nat	Art	Nat	Art	Nat
9-month	2	12	0.657	0.885	0.499	0.550	0.918	0.586	0.380	1.554
12-month	3	13	0.443	0.543	0.235	0.284	0.404	0.212	0.577	1.632
18-month	5	13	1.149	0.838	0.614	0.310	0.733	0.322	0.949	1.705
24-month	9	14	1.284	0.971	0.607	0.375	0.622	0.358	1.276	1.778
36-month	12	11	1.714	0.566	0.775	0.202	0.690	0.232	1.777	1.481
48-month	8	****	1.526	****	0.659	****	0.735	****	1.187	****
60-month	13	****	1.349	****	0.556	****	0.526	****	1.578	****

Scleractinian size class distribution at the natural hardbottom areas remained relatively unchanged from 9-months to 36-months post-deployment (Fig. 2). In general, the artificial reef scleractinian size class structure experienced steady increases in the three smallest size classes from 9-months to 48-months. Between 48-months and 60-months, the smallest size class (1-2 cm) experienced a five-fold increase and the 3-5 cm and 6-15 cm size classes experienced a three-fold increase, resulting in similar scleractinian size class structures at the artificial and natural habitats 60-months post deployment (Fig. 2).

Octocoral community

Results from the MDS show that the octocoral community at the natural hardbottom sites has remained stable overtime, whereas, the community on the artificial reef has gradually become more similar to the natural hardbottom community from 9-months to 48/60-months post-deployment (Fig. 3). Results from the SIMPROF indicate that by 48/60-

months post- deployment, the octocoral community on the artificial reef is 63% similar to that of the natural hardbottom sites (Fig. 3).

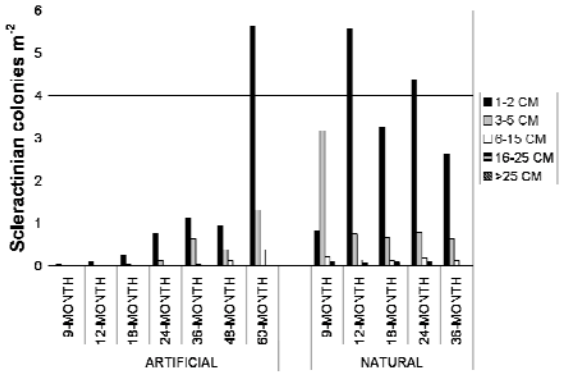

Figure 2: Scleractinian size class distribution on artificial reef and natural hardbottom for each monitoring period.

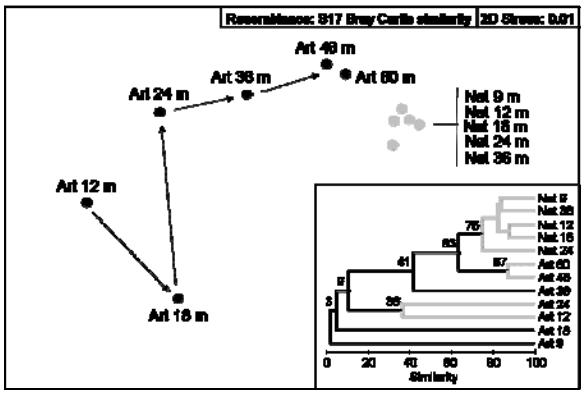

Figure 3: Two-dimensional MDS plot and corresponding SIMPROF dendrogram based on octocoral abundance m^{-2} of hard substrate. Monitoring groups connected by grey lines cannot be significantly differentiated ($p \leq 0.05$). Nine-month artificial reef monitoring event is not depicted in this figure, as the distance between it and all other subsequent events was too great to fit.

Species richness at the natural site remained stable throughout monitoring, between 8 and 11 (Table 2). Species richness at the artificial reef was 11 by the end of monitoring, equaling that of the natural sites. Diversity indices indicate that octocoral diversity on the artificial reef increased steadily, and by 60-months post-deployment resembled diversity observed on the natural reef (Table 2).

The artificial reef octocoral size class profile by 48/60-months post-deployment resembles that of the natural hardbottom, however, octocoral abundance was still greater at the natural sites than the artificial reef (Fig. 4). The abundance of octocoral recruits (1-5 cm) increased steadily throughout monitoring, while the level of recruitment on the natural hardbottom remained relatively constant.

Table 2: Measures of octocoral diversity on artificial reef and natural hardbottom.

Discussion

The Broward County artificial reef has succeeded in providing suitable habitat for recruitment and development of scleractinian and octocoral communities. These developing communities are becoming more similar in abundance, diversity and size class structure to the communities found on the adjacent natural hardbottom over time. As the MDS's suggest, by 60-months post-deployment, the scleractinian and octocoral communities on the artificial reef appear to be developing at slightly different rates, with the scleractinians and octocorals reaching 70% and 63% similarity, respectively, to the natural sites.

It is unclear why the scleractinian community appears to be more established, especially considering that only 5% of scleractinians on the natural hardbottom have reached reproductive size (>5 cm), while 30% of octocorals in the natural population are reproductive (>20 cm) (Bak and Engel 1979; Soong 1993; Gutiérrez-Rodríguez and Lasker 2004). It would be expected that this proportional difference in reproductive adults on the natural hardbottom would directly influence the level of recruitment onto the adjacent artificial reef. This reasoning seems to explain the observed trends until the last monitoring event: from 48-months to 60-months post-deployment, the scleractinian community at the artificial reef experienced a four-

fold increase in overall abundance and a five-fold increase in recruits (1-2 cm).

It is well understood that hurricanes or severe storms can reduce coral recruitment rates (Connell 1997); considering this in context of South Florida's active 2004 and 2005 hurricane seasons (corresponding to the 12-month and 24-month monitoring events) may explain the low recruitment levels leading up to 60-months post-deployment. A second explanation for the delay in high scleractinian recruitment levels could be related to time needed for organisms that produce chemical cues and substrate that enhance coral settlement to the artificial reef (e.g. crustose coralline algae) (Morse and Morse 1984; Vermeij and Sandin 2008).

Although this data shows that both the scleractinian and octocoral communities on the artificial reef are becoming increasingly similar to those on the natural hardbottom, structural differences between the low-relief natural nearshore habitat and the high-relief limestone boulders of the artificial reef are expected to lead to distinct climax communities (Baynes and Szmant 1989; Glasby and Connell 2001; Perkol-Finkel et al. 2006). The elevated surfaces of the limestone boulders will likely permit some species of corals to persist and grow that are unable to tolerate the ephemeral nature of the low-relief natural hardbottom. It is expected that the artificial reef will develop a climax community that will be more diverse than that on the natural hardbottom, and may include larger individuals and more colonies than found on natural hardbottom habitat. However, to date, the Broward artificial reef is succeeding as mitigation for natural hardbottom by harboring a coral community that continues to increase in resemblance to that of the adjacent natural hardbottom coral community.

Development of a coral nursery program for the threatened coral *Acropora cervicornis* in Florida

J. Herlan, D. Lirman

University of Miami, 4600 Rickenbacker Causeway, Miami, FL 33143, USA

Abstract. The staghorn coral, *Acropora cervicornis*, was once a dominant reef-building species throughout the Caribbean region. Due to hurricanes, disease, and other human and natural stressors, its populations have declined dramatically in the last few decades. In an attempt to propagate this species for local restoration efforts, coral gardening was initiated in Florida, USA in 2007. Branches of *A. cervicornis* were clipped from donor adult colonies from Biscayne National Park and cemented onto cinder blocks in an underwater nursery. Eighty-eight fragments were monitored regularly during the first four months after transplantation to evaluate patterns of mortality attributable to the collection and transplant methods and to assess initial patterns of growth. Fragment mortality of 17.3% was documented for the first 8 weeks after transplantation, but decreased to <1% in subsequent monitoring intervals. Although there was no significant difference in growth rates between fragments glued in horizontal and vertical position, larger-sized fragments (> 5 cm) grew significantly faster than small (< 3 cm) and medium (3-5 cm) fragments.

Key words: coral gardening, coral nursery, *Acropora cervicornis*

Introduction

The scleractinian coral *Acropora cervicornis* was once a dominant building species in Caribbean coral reefs during the past 500,000 years (Jackson 1994). This species, however, has experienced drastic population declines (>95%) during the last three decades attributed to multiple factors that include increased sea-surface temperatures and associated bleaching, hurricanes, and white band disease (Bruckner and Hourigan 2002). The recent decline of *A. cervicornis* across its full range has prompted the listing of this species as 'threatened' under the U.S. Endangered Species Act in 2006. Furthermore, this species relies heavily on asexual reproduction via fragmentation and has limited success in sexual recruitment, demographic attributes that slow population recovery beyond local habitats (Bak and Engel 1979; Tunnicliffe 1981; Knowlton et al. 1990; Vargas-Angel et al. 2003). The local conservation of *A. cervicornis* populations as well as the build-up of stocks via active restoration can potentially improve recovery by enhancing rates of sexual recruitment (Vollmer and Palumbi 2007).

In the last decades, "coral gardening" (Rinkevich 1995, 2000, 2005; Bowden-Kerby 2001; Epstein et al. 2001; Shafir et al. 2006) has become an increasingly important tool in reef restoration. Coral gardening consists of growing corals in-situ at a nursery site, and then transplanting these coral fragments back onto natural reef environments once they have grown to an appropriate size (Rinkevich 1995, 2000; Epstein et al. 2001; Shafir et al. 2006). Coral gardening has been undertaken using varied methods of fragment or nubbin attachment such as mid-water wire frames, floating platforms, concrete, and suspended lines (Bowden-Kerby 2001; Shafir et al. 2006).

In this study, we describe the initial stages of a local attempt to enhance staghorn coral populations in Florida, USA. The gardening approach used in this study consisted of collecting fragments of *A. cervicornis* from adult colonies and growing these fragments in a coral nursery established within Biscayne National Park, Florida. Due to the depletion of *A. cervicornis* in Florida, the goal of this project is to collect minimal tissue from adult colonies (thereby limiting further depletion of adult stocks) and establish a methodology to maximize growth and survivorship of fragments to provide an expanding source of coral tissue for future restoration activities.

Here we report initial patterns of fragment survivorship and growth based on initial fragment size and orientation of attachment to transplant platforms. This study concentrates on the time period immediately following collection and transplantation of fragments to document directly the impacts of the collection, transportation, and cementation methods on fragment growth and survivorship. Based on the source of stress to the fragments collected, it was hypothesized that fragment mortality would be high initially but would decline with time as fragments

cemented themselves to the platforms and the regrowth process began. Initial high mortality followed by reduced mortality rates of surviving fragments were documented in other coral transplant experiments (Clark and Edwards 1995; Quinn and Kojis 2006).

Material and Methods

Staghorn coral nurseries in Florida

The nursery described in this study is part of a network of four staghorn nurseries established in the Florida Reef Tract from Broward County to the Middle Florida Keys using uniform methods (Nedimeyer and Johnson, unpublished). After a period of growth (6 mo – 1 yr) at the nurseries, the fragments will be transplanted to different habitats where staghorn corals were once abundant as well as habitats damaged by ship groundings.

Coral fragments

Donor adult *A. cervicornis* colonies were located at 11 different sites within Biscayne National Park. Coral fragments were carefully collected from the donor colonies using pruning scissors (Fig. 1).

The nursery

The nursery is located at 6 m depth in Biscayne National Park, Florida, US (25º 21.753′ N, 80º 9.985′ W). A sand patch adjacent to a reef was used to deploy a matrix of 30 cinder blocks. Each block contained a maximum of 10 vertical cement cylinders with a cement "puck" attached at the top (Fig. 1). The fragments were mounted to the puck using underwater epoxy. Identification codes were marked on the pucks using a stone engraver, black marker, and a coat of fiberglass resin. The cement pucks were designed so that the whole unit can be transplanted back to the various reef habitats after a period of regrowth without the need to handle the colonies. The pucks themselves will be cemented to the reef bottom at the future transplant sites.

In this study, we report growth data for 88 fragments that were measured regularly during the initial 4 months after transplantation (June to October 2007). Fragments were divided into 3 size classes: small (<3 cm in max length), medium (3-5 cm), and large (>5 cm). Within each size class, fragments were positioned either horizontally or vertically on the pucks (Fig. 2). At each survey, the cinder blocks were scrubbed clean with wire brushes to limit algal overgrowth and sediment accumulation.

Figure 1: Photographs depicting the steps in the coral gardening approach used in this project. 1) Adult *A. cervicornis* colonies. 2) Fragmented colony. 3) Fragment from which smaller sections were cut. 4) Nursery platform with transplanted fragments.

Monitoring and maintenance

Numerous studies have correlated coral growth and survivorship with colony size (e.g., Hughes 1984). For branching corals with complex morphology, it is often impossible to estimate whole-colony size (and growth) in the field and researchers have used the growth of a subset of branches as a proxy of whole-colony growth. In this study, the fragments used had a simple initial morphology (a single cylindrical branch) or simple branching morphology (maximum of 4 branches by the end of the study period). Thus, it was possible to measure and report the initial size and growth of fragments by calculating the sum of all branch lengths. This approach was used successfully to assess growth of *A. cervicornis* fragments and colonies by Bowden-Kerby (2001) and Quinn and Kojis (2006). As colonies grow in complexity, growth patterns will likely need to be assessed by measuring the average linear extension of a subset of marked branches. Patterns of linear growth were compared among fragments with a two-way ANOVA with size and orientation as main factors.

Results

A fragment mortality of 17.3% was documented in the first 8 weeks after transplantation. However, a large portion of this mortality (9.2%) was recorded during the first 3 weeks after transplantation. Mortality decreased to <1% of the remaining fragments during subsequent surveys (Fig. 3). No significant differences in the mean size of the surviving (4.4 cm ± 2.1) and dead fragments (4.1 cm ± 1.3) were observed during the first 8-week period ($p > 0.05$, *t* -test).

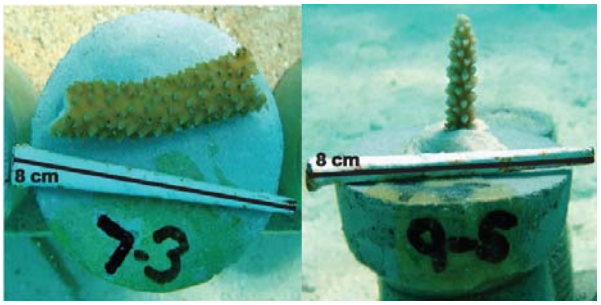

Figure 2: Photographs of staghorn corals cemented in horizontal and vertical growth position.

Fragment growth during the first four months after transplantation was influenced by initial fragment size. There was a significant difference ($p < 0.05$) amongst the linear extension rates of the 3 size classes, with the larger size class growing faster than the smaller ones (Fig. 4). Although fragments placed in horizontal position generally grew faster that those placed in vertical position (except for the smallest fragments), these differences were not significant. Lastly, no significant interaction was found between fragment size and orientation ($p > 0.05$).

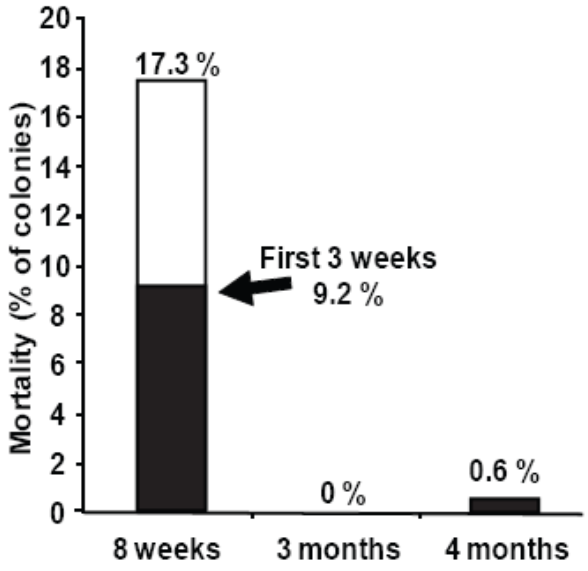

Figure 3: Mortality of fragments transplanted onto the coral nursery.

Discussion

The initial stages of the coral gardening program implemented for *A. cervicornis* in Biscayne National Park have been encouraging and this approach has the potential to become an important tool to provide an expanding stock for future local reef restoration efforts. Moreover, the combination of relatively low initial mortality and fast growth rates of fragments demonstrates that staghorn corals could be appropriate for a coral gardening program in Florida.

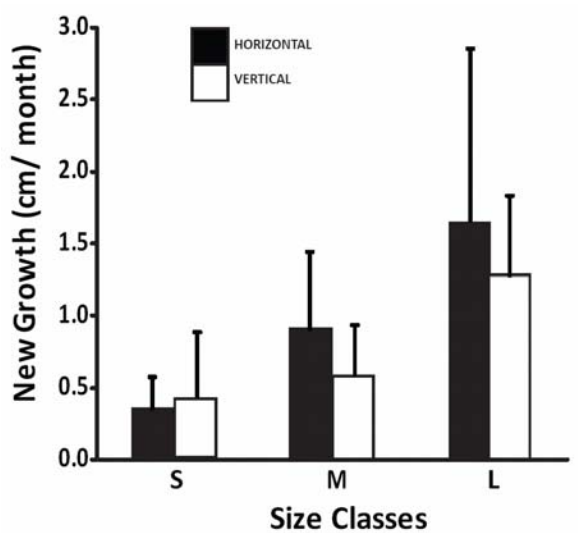

Figure 4: Mean growth (± SD) of transplanted staghorn fragments based on initial size and orientation.

Previous attempts to establish nurseries with staghorn corals provided initial fragment mortality estimates of 22% and 27% (average of 4 sites, recorded 6 and 11 weeks after fragmentation respectively) (Quinn and Kojis 2006). These mortality estimates are comparable to that in our nursery (17.3% after 8 weeks).

In the absence of major disturbances, the highest levels of mortality are commonly recorded during the first observation period following fragmentation, with mortality rates decreasing over time as fragments attach to the substrate and grow (Clark and Edwards 1995; Bowden-Kerby 2001). In agreement with these studies, the largest proportion of the mortality recorded took place within the first few weeks after transplantation (9.2% of fragments died within the first three weeks), and mortality rates decreased thereafter, indicating that the environmental conditions at the nursery site are adequate for fragment survivorship and growth. Likely factors influencing the early mortality patterns observed include stress due to fragmentation and high-temperature impacts. Initial fragmentation for this nursery was done during June and July of 2007, when sea surface temperatures were high (29–30ºC). Based on these observations, we concluded that, when possible, the fragmentation step of coral gardening should be performed when most other extraneous stressors, like high temperature, are minimized. .

The size of fragments is commonly associated with rates of survivorship and growth (Lirman 2000). In this study, fragment mortality was not associated with fragment size (for the range of sizes collected) but larger fragments exhibited faster initial growth rates compared to smaller fragments. This information is

important to determine the minimum size of fragments to collect for a gardening program. The faster growth rates of the horizontal fragments were unexpected because more living tissue from the bottom portion of these fragments was lost initially due to the contact with the epoxy and the cement base. However, fragments placed in a horizontal position have at least two terminal ends for potential new growth and branch development. By being able to extend from the additional growing end (compared to vertical fragments), horizontal fragments grew initially faster than vertical fragments. The continued monitoring of fragment growth will determine whether the initial faster growth rates of horizontal fragments is maintained over time as fragments develop complex branching patterns.

Maximizing growth rates of transplanted corals is a key goal of gardening programs. In this study, the maintenance conducted to remove sediments, macroalgae, and other coral competitors provided enhanced growth conditions for fragments. Under these conditions, the growth rates of staghorn fragments measured in the nursery compared favorably with the linear extension of adult staghorn colonies (10-15 cm/year) reported previously (Gladfelter 1984), indicating that even small fragments are capable of rapid growth rates when potential sources of competition and stress are removed periodically.

The propagation of *Acropora cervicornis* via a coral gardening approach implemented within in-water nurseries using low-cost materials (e.g., cement, epoxy, cinder blocks), can provide an effective method to expand declining stocks of the threatened staghorn coral in Florida. The results that help classify this new program as successful in its early stages include: (1) limited initial fragment mortality (< 20% of fragments were lost in 2 months following fragmentation); (2) rapid decline in subsequent mortality (< 1% between 2 and 4 months); and (3) rapid growth of even the smallest of fragments. The ultimate success of these restoration efforts will depend on the continued growth of fragments as well as the viability of nursery-reared colonies once transplanted back onto natural reef sites.

Coral relocation for impact mitigation in Northern Qatar

D. Kilbane[1], B. Graham[1], R. Mulcahy[1], A. Onder[2], M. Pratt[2]

1) CSA International Inc., Stuart, Florida, USA
2) Qatar Liquefied Gas Company Limited (II), Doha, Qatar

Abstract. A large-scale, long-distance coral relocation project was conducted as mitigation for impacts to hard coral habitat associated with marine construction activities offshore Ras Laffan Industrial City, Qatar. Working under the guidance of the Supreme Council for the Environment and Natural Reserves, Qatargas Operating Company Limited and its Venture partners engaged in a hard coral relocation project. The project salvaged and relocated over 4,500 hard corals from pipeline corridors to mitigate for pipeline installation impacts. Proven techniques for coral reattachment and newly developed methods to enhance coral survival were used for the mass recovery, transport, and reattachment of the corals. Corals were transported 46 km, a single day transit, from the north coast of Qatar to a coral habitat along the east coast and reattached with concrete. Initial monitoring of approximately 5% of the reattached corals and randomly selected reference corals indicates high survival rates. This project represents an option for off-site mitigation and is an example of proactive environmental regulation, corporate responsibility, and advanced field technology applied in concert to reduce impacts to a viable hard coral habitat.

Key words: Off-site mitigation, Coral relocation

Introduction

Qatargas Operating Company Limited (QG) and its Expansion Projects (i.e., Qatar Liquefied Gas Company Limited [II], Qatargas 3 and Qatargas 4 Joint Asset Development Team [QG3&4], and Common Condensate Single Point Mooring [SPM] Project) are installing five export pipelines within three corridors offshore the coast of Ras Laffan Industrial City (RLC), Qatar to expand their production capabilities in the Arabian Gulf.

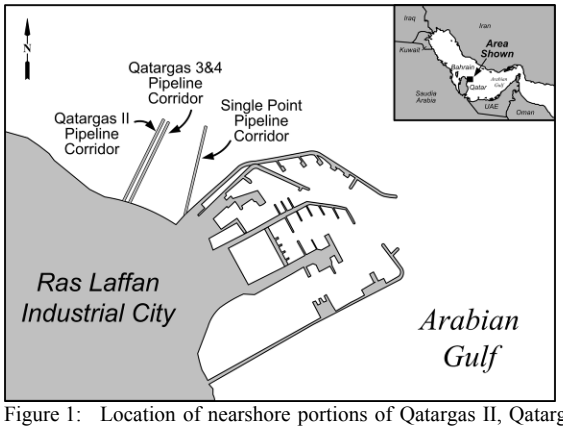

Figure 1: Location of nearshore portions of Qatargas II, Qatargas 3&4, and Common Condensate Single Point Mooring (SPM) pipeline corridors relative to Ras Laffan Port.

The pipelines will be installed on the seafloor from the offshore platforms to a point 2.5 km offshore RLC (Fig. 1). From 2.5 km offshore to the pipeline landing, the pipelines will be buried in three 7-m wide trenches. It was estimated that pipeline burial activities would affect a 50-m wide area along the 2.5-km distance for each pipeline corridor.

The Arabian Gulf, a semi-enclosed shallow sea, supports many complex and unique hard coral habitats. The Gulf is connected to the Indian Ocean by the Straits of Hormuz and experiences some of the widest seasonal fluctuations in water temperature and salinity recorded anywhere in the world. Gulf corals have adapted to fluctuations in temperature ranging from 10°C to 40°C and salinity changes from 28 to 60 ppt (Pilcher et al. 2000). Therefore, many endemic species are found in the Arabian Gulf but overall the coral habitats have low biological diversity. Recent bleaching events attributed to extreme high water temperatures occurred in 1996, 1998 and 2002 and reduced coral cover to less than 1% in many of the shallow water areas (Rezai et al. 2004).

The slow growing hard coral populations, which have only begun to recover from these bleaching events, are also threatened by anthropogenic impacts. Corals in sensitive coastal habitats are affected by turbidity and suspended sediments from land reclamation and dredging projects. Cooling water discharged from desalination and power plants exposes coral habitat to heated effluent water, generally 10°C above ambient temperatures, and toxins including anti-fouling and anti-scaling

chemicals. Nearshore construction projects for the oil and gas industry also threaten sensitive coral reef habitats.

The proposed new pipeline routes for Qatargas Expansion Projects cross sensitive coral habitats offshore RLC. The proposed pipeline corridors were surveyed in 2004 and 2006 to characterize habitats that would be affected by pipeline installation activities. The nearshore portions (defined as approximately 1.2 to 2.5 km offshore) of each of the pipeline corridors were characterized by low-relief hard bottom substrate and a biological community that includes hard corals at an average density of 0.47 colonies m^{-2} (Continental Shelf Associates Inc. 2005a, b, 2006a).

Based on the habitat characterization surveys, a Coral Management Plan (CMP) was prepared, approved by the Supreme Council for the Environment and Natural Reserves (now the Ministry of Environment), and implemented to mitigate the unavoidable impacts of pipeline installation activities to this sensitive habitat. The CMP recommended the reduction of biological impacts by salvaging and transplanting hard corals affected by pipeline installation rather than the alternative of compensating for destroyed corals by creating artificial reef habitats. Based on the observed average live hard coral density and coral relocation experience from other areas, approximately 4,500 hard corals were relocated from the area to be dredged to a fasht (shallow, emergent rock marine outcrop) coral habitat along the east coast of Qatar (Continental Shelf Associates Inc. 2006b).

Materials and Methods

Reattachment area

Water depth measurements, temperature and salinity water column profiles, substrate classifications, general habitat observations, and video and still photographs were collected at eight sites along the east coast of Qatar to determine the most suitable site for coral reattachment activities. Site 7 (25°33' 02.00"N, 051°37'22.50"E), known locally as the Fasht al Hurabi, was selected as the most suitable site for reattachment activities. The Fasht al Hurabi area is a crescent-shaped, 1–5 m deep, gently-sloping rock outcrop with strong north-to-south running currents. The coral community was historically diverse and thriving, and suffered mass mortality in the last decade likely due to elevated seawater temperature anomalies that occurred in the region. Since that time, recovery of this community has been slow, as reflected by the lack of acroporid branching corals (*Acropora* spp.) and the dominance of available hard substrate by opportunistic massive coral species (*Cyphastrea microphthalma* and *Porites harrisoni*) and associated biota. Coral skeletal remains indicate a once flourishing *Acropora* dominated coral community in shallow water at depths of 2–3 m, transitioning to a more massive coral species dominated community comprising the genera *Porites* and *Platygyra* at depths of 3–5 m.

Coral removal

A total of 4,517 coral colonies was chosen for removal based on a general set of criteria, i.e., selected colonies must be 1) representative of the species and densities present within the pipeline corridors; 2) greater than or equal to 10 cm in diameter; 3) preferably mounding and boulder growth forms rather than encrusting forms; and 4) relatively healthy with no obvious disease, bleaching, or partial mortality. Selected colonies were removed by shearing the coral/substrate attachment point using a hammer and masonry cold chisel and lifting the colony off in one piece, to the extent possible. Each coral colony was carried by hand or in a bucket to a 2 m x 2 m metal transport tray, where it was cached *in situ* in a single layer until all corals were detached and ready for transport to the relocation site. Once all corals had been cached, the transport trays were prepared for recovery by attaching a buoyed lifting bridle and small meshed covering to each of the transport trays.

Coral transport

A 33.5-m landing craft was used to transport the corals a distance of 46 km from the removal area to the relocation area. Approximately 2,250 corals were transported per transit to the relocation area. To maintain corals in ambient temperature seawater and a dark environment during the day-long transport, a large (44-m^2) covered circulating seawater pool was constructed on the deck of the transport vessel (Fig. 2). A large crane was used to bring cached coral colonies to the surface in the transport trays and place them in the pool on board the transport vessel. The pool was covered during transit to the relocation area to prevent or reduce stress to the corals from overheating and excessive solar illumination. Once at the relocation area, the filled transport trays were removed from the pool and lowered to the seafloor with the large crane. Once the transport trays were stable on the seafloor, transport bridles and nets were removed by scientific divers. Global positioning system (GPS) coordinates were recorded for each on-bottom transport tray cache location.

Coral reattachment

Corals were reattached with specialized concrete at 22 sites within the reattachment area (Fig. 3). Prior to attaching corals, the attachment surfaces of both the

coral and the selected receiver site were prepared by removing loose surficial debris and biota (i.e., algae and fouling organisms) to ensure proper bonding with the concrete. Manageable amounts of sand and cement were mixed in plastic buckets on the deck of support boats and then lowered to divers who placed sufficient amounts of concrete directly on the pre-cleaned substrate. The non-living base of the detached coral colony was then pressed firmly into the concrete mixture. Attached corals were checked periodically during reattachment operations to ensure their stability, address the aesthetic quality of the reattachment matrix, and dissipate cement residue that may have settled on adjacent living coral tissue and biota.

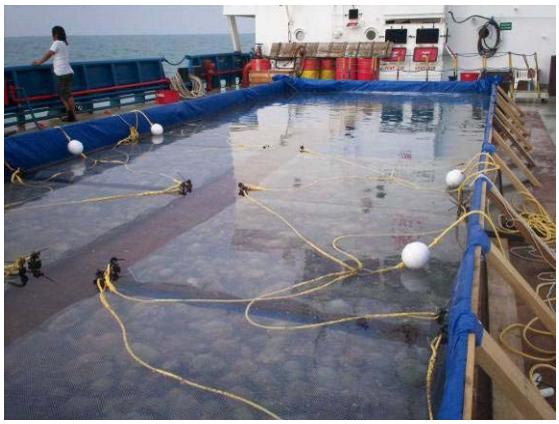

Figure 2: Loaded transport trays within the circulating seawater pool on the deck of the transport vessel.

Monitoring

Six of the 22 reattachment sites were randomly selected to bi-annually monitor the success of the coral relocation project and to assess and record detectable changes in the benthic community structure (Fig. 3). A subset of the relocated corals (approximately 5%) and natural (reference) corals were randomly selected, uniquely tagged, and mapped to monitor the relative coral health and success of the reattachment activities (Fig. 4). *In situ* observations of colony health and status of the cement bond as well as scaled digital photographs were collected for each monitored colony during all monitoring surveys. Four permanent 10-m transects were established at each of the monitoring sites to quantitatively document temporal changes in seafloor habitats and the associated benthic community. Temperature data loggers were installed to continually record seawater temperatures between monitoring surveys.

Results and Discussion

Hard coral colonies within the pipeline corridors generally were less than 30 cm in diameter with mounding or boulder morphologies that enabled the removal and reattachment of intact colonies. Relocated colonies ranged in diameter from 10 to 35 cm from seven species with mounding or boulder morphologies. Fragmentation of colonies was avoided because branching colonies were not encountered and the colonies were relatively small and manageable. Additionally, colonies were not fragmented as transplantation of large fragments or whole colonies has a greater likelihood of success compared to small fragments (<10 cm) (Plucer-Rosario and Randall 1987; Harriott and Fisk 1988; Edwards and Gomez 2007).

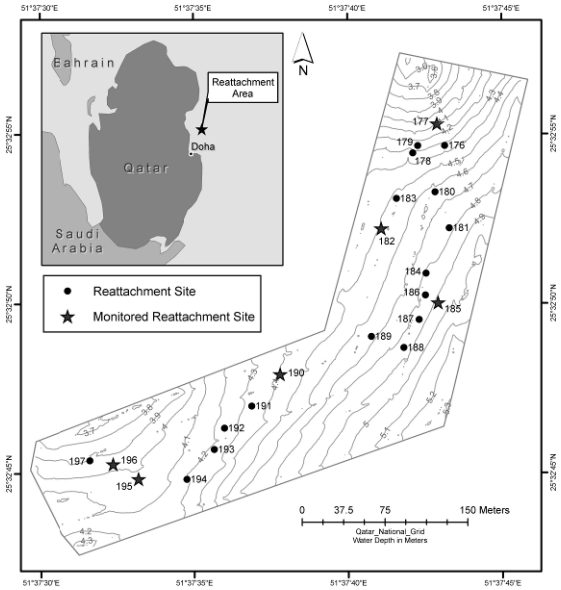

Figure 3: Coral reattachment and monitoring sites relative to the bathymetric contours at Fasht al Hurabi.

Figure 4: Monitored reattached colony of *Platygyra lamellina*.

Reattachment activities were completed in February 2007 with 4,548 colonies (4,517 transported colonies and 31 additional colonies found loose at the reattachment area) from seven species reattached at 22 sites at Fasht al Hurabi (Fig. 3).

The attachment status and relative health of 285 reattached colonies and 101 natural (reference) colonies was monitored bi-annually to assess the success of the relocation project (Table 1). After one year, 99% of the reattached monitored colonies survived compared to 79% survival of reference colonies, and a greater percentage of reattached colonies were healthy (58%) when compared to reference colonies (33%) (Fig. 4). The greater percentage of dead and unhealthy reference colonies compared to reattached colonies may be due to smothering from increased sedimentation observed during the 12-months post-reattachment survey since natural colonies are often located near the bases and sides of rocks. Coral colony health declined during the period between the 6-month and 12-month post-reattachment surveys. The decline was observed in both reattached and reference corals, which may be attributed to increased stress during the winter months due to extreme sustained low sea water temperatures documented by the on-site temperature data. Low temperature events and adverse effects on corals have previously been documented in the Arabian Gulf (Coles and Fadlallah 1991). Additional stressors experienced across the reattachment area during the month of February included increased sedimentation and a seasonal bloom of the brown alga *Colpomenia sinuosa* (Coles 1988).

Table 1: Summary of monitored coral colonies by species.

Scientific Name	Reattached	Reference
Anomastraea irregularis	10	1
Cyphastrea microphthalma	4	51
Favia sp.	123	8
Platygyra lamellina	46	12
Plesiastrea versipora	45	4
Porites harrisoni	55	18
Pseudosiderastrea tayami	2	7
Total	285	101

The benthic community was dominated by turf algae during the summer 2007 survey (6 months post-reattachment) and by *Colpomenia sinuosa* during the winter 2008 survey (12 months post-reattachment). Hard corals and other fauna (e.g., sponges and oysters) combined provided less than 12% cover during both surveys. Average hard coral density was low at all sites, ranging from 1.8 to 2.5 colonies/m^2, a slight decrease from 6 months post-reattachment (2.3 to 2.7 colonies/m^2).

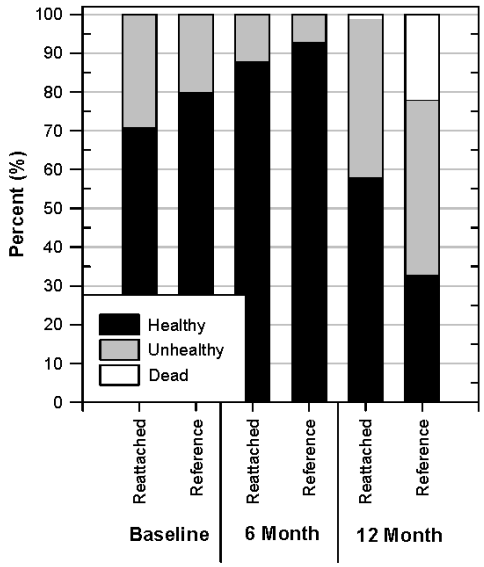

Figure 4: Comparison of the percent of healthy, unhealthy, and dead monitored colonies among monitoring surveys.

Seawater temperatures were similar at all of the monitoring sites, ranging from a high of 36.1°C in August 2007 to a low of 14.4°C in January and February 2008 (Fig. 5), representing a temperature range of 21.7°C. This range in water temperature is similar to the extreme temperature range previously documented on coral reefs in Qatar (Shinn, 1976) and is one of the greatest temperature ranges recorded on high latitude coral reefs. Minimum water temperatures fell below 18°C for 4 consecutive days in December (28 to 31 December 2007) and for 37 consecutive days beginning 7 January 2008 until 13 February 2008. During the latter extreme low water-temperature event, colonies were exposed to water temperatures below 16°C for 8 consecutive days in January (15 to 22) and again in February (1 to 8).

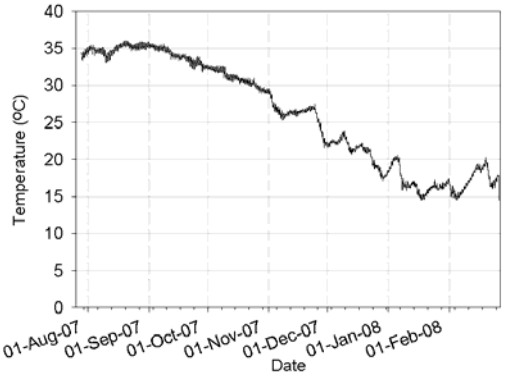

Figure 5: Continual seawater temperature data recorded from 27 July 2007 to 26 February 2008.

Conclusions

The results of this project indicate that hard coral relocation is a viable means of off-site mitigation for unavoidable impacts to sensitive coral habitats. After 1 year, 99% of monitored reattached colonies have survived. Although previous monitoring studies (Yap et al. 1992; Yap 2004) indicate that 1 year is an adequate period of time to evaluate the response of reattached corals to environmental conditions, biannual monitoring will be continued for at least two years following the transplantation to further assess the success of the relocation effort.

This successful project provides a benchmark for off-site mitigation that environmental regulators may utilize as a viable option for minimizing direct impacts to hard corals from offshore construction activities. Coral relocation in Qatar has been used as mitigation on another construction program based on the relative success of this project (CSA International Inc. 2008). Reattachment sites for future relocation activities should be carefully selected with similar environmental conditions (depth, temperature, salinity, turbidity, and benthic habitat type) to those at the removal site to increase the likelihood of coral survival. If possible, future relocation projects should consider conducting relocation activities during mean water temperatures to minimize stressful environmental conditions immediately after reattachment.

Abstract. Following observations of natural recruitment of coral colonies to breakwaters in Naha Port, Okinawa Prefecture in 1989, we launched monitoring surveys to explore the processes of coral settlement and growth on concrete armor blocks, along with the development of technology to enhance coral settlement and growth on such structures. The development concept centered on creating rough surfaces on conventionally smooth block surfaces, thus imitating the natural rugosity of reef substrates. In 1999, the findings from these surveys and experiments were then applied to the project "Eco-block", a wave-dissipating block with unevenly processed surfaces to enhance coral recruitment. Since the installation of Eco-blocks, the growth and recruitment of corals on the blocks has been recorded yearly. Eco-blocks with surface abrasions at about 5mm and 10mm in depth and width had higher coral settlement compared to unprocessed blocks.

Key words: coral restoration, port development, artificial structure, surface processing, increased settlement

Introduction

Coral communities are widely recognized for the crucial roles they play in subtropical and tropical coastal ecosystems (Costanza et al. 1997; Moberg et al. 1999). Among the world's coral reef seas, the southern area of Japanese waters surrounding the islands of Okinawa Prefecture has been described as a biological hot spot, an area with high diversity and a multitude of rare species (Roberts et al. 2002). Coral communities found in this area were extensively damaged following a severe bleaching in 1998, which was induced as a result of abnormally high sea temperatures (Hoegh-Guldberg 2000). These corals are now showing signs of recovery; yet, it is crucial to gain an insight into the coral growth and settlement before and after the bleaching event, as well as the development of restoration technologies to facilitate the recovery of corals from bleaching.

The Okinawa General Bureau, the Cabinet Office of Japan, also spare no efforts in promoting port development, in which port or harbor modification should follow "coral friendly" approaches. In 1989, coral colonies were found settled on wave-dissipating blocks of Naha First Breakwater in Naha Port. Every year since 1990, the settlement and growth of corals have been monitored annually on 30 fix quadrates. The results compiled until 2003 were reported by Ooka et al. (2006). In addition, focusing on this phenomenon as a way to make port construction more coral-friendly, we began the development of technology to enhance coral settlement and growth on concrete armor blocks. The development concept centered on creating roughness on conventionally smooth block surfaces, thus imitating natural substrates as near as possible. The initial experiment began in Naha Port in 1990, followed by the second one in 1991. The findings from these experiments were then applied in a project utilizing the "Eco-block" in 1999, a wave-dissipating block with abrasive protrusions on its surface. Since the installation of Eco-blocks, the growth and settlement of corals have been monitored yearly in 36 fixed quadrates placed on them. In this report, we analyzed the findings from these surveys and evaluated the effectiveness of such uneven processing on block surfaces in enhancing coral settlement.

Methods

Monitoring of coral settlement and growth: wave-dissipating blocks without surface processing

The purpose of this monitoring is to explore the coral settlement and growth on the unprocessed, smooth surfaces of artificial substrates. The surveys were conducted around Naha First Breakwater in Naha Port,

Japan. Live coral coverage and number of colonies were monitored annually over eight years between 1990 and 1997 at six different water depths C.D.L. (Chart Datum Level) -1, -3, -5, -7, -9 and -12m). The data were collected from three stations set up at each depth, and year-on-year changes were observed and reported (Yoshimi et al, 1998). The monitoring was then resumed in 2000, in response to the coral degradation caused by the bleaching in 1998, an extensive bleaching associated with unprecedented high sea temperatures around the world. The surveys were conducted on the same stations until 2007.

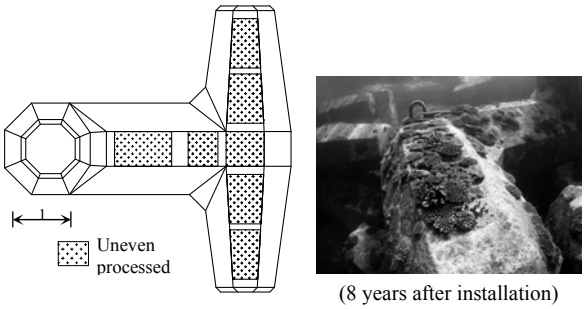
Monitoring of coral settlement and growth on Eco Blocks: experiment to enhance coral recruitment

Eco Block development

To gain an insight into the relationships between substrate properties and coral settlement, we conducted the experiment in two locations using armor blocks with different surface modifications. In 1990, we deployed our blocks with surface protrusions to the height of 1cm onto the side of Naha First Breakwater (primary experiment section), and in the following year of 1991, deployed another type of blocks with triangular or rectangular patterns etched out into the surface onto the side of Naha Breakwater (secondary experiment section). Coral settlement was monitored annually on these blocks by underwater visual observation. The results showed an enhanced attachment of the corals, proving the effectiveness of such modification (Iwakami et al. 1995; Yoshimi et al. 1998). These results in turn saw the development of the "Eco Block," a wave-dissipating block designed to enhance coral settlement, and the launching of an ongoing project using such blocks in Naha Port, from 1999 onwards. The Eco Block's surface (Fig. 1) is unevenly processed in various shapes and patterns when molded in factories.

Monitoring of coral growth on Eco Blocks

The monitoring commenced in 1999 on Eco Blocks placed around Naha Breakwater and continued until 2007. Fixed stations were set up on the top surface of the blocks. Block surfaces were classified into four levels of surface roughness: abrasions in the region of 2mm, 5mm, and 10mm in depth and width, and unprocessed (for control). On the surface of each roughness processed by using some kinds of wood frame while the surface of the concrete was soft, three quadrates (50cm x 50cm) were placed at each depth of C.D.L.-2, -5, and -8m, and the number of colonies, coral cover, number of species and maximum diameter in a quadrate were documented by underwater visual observation.



(8 years after installation)

Figure 1: Eco-block (40t)

Results

Coral settlement and growth on unprocessed blocks

As the fixed monitoring stations were set up on the blocks installed in 1986, the survey marked the twenty-first year in 2007. Figure 2 shows year-on-year changes of coral cover and the number of colonies by water depth. Graphs represent mean values and standard deviation (n=3) of the data obtained from the top surfaces (gradient: 0°).

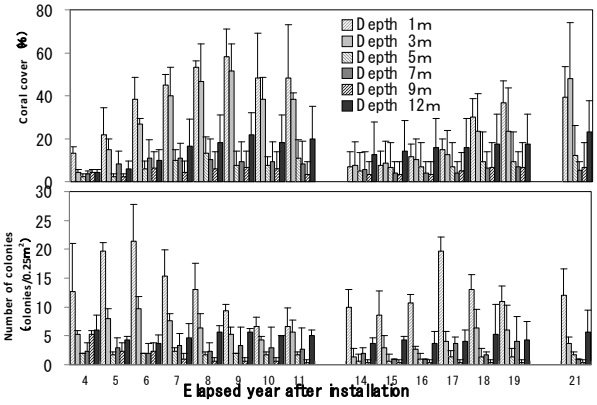


Figure 2: Coral growth on artificial blocks at Naha port. The blocks were installed in 1986. (Mean+SD: n=3)

Changes in number of colonies

At the depths of C.D.L.-1m and -3 m, both the number of colonies and coral cover increased over the period spanning the fourth year (the initial year of the survey) to the sixth year following block installation. Meanwhile, from the seventh to ninth years, the number of colonies was decreasing while the coral cover in the same period was increasing. At the depths of C.D.L.-5m and deeper, the number of colonies remained at relatively low levels, indicating that poorer light conditions in contrast to that at shallower depths (C.D.L.-1 and -3m) slowed coral growth, with minimal competition among the colonies over substrate space.

With regards to the results subsequent to the 1998 bleaching event (the 12th year post installation), no significant changes were observed in colony numbers between the 14th and 16th years. This implies lower

rates of larval recruitment immediately after the bleaching. But in the 17th year, the number of colonies increased, especially at the depth of C.D.L.-1m, with the colonies almost doubling in number. In the 18th year, although the number of colonies dropped notably at C.D.L.-1m, the coral cover showed a continued increase, suggesting the growth of the colonies that had settled in the previous year.

Changes in coral cover

From the 14th year of the survey onwards, the coral cover on all wave-dissipating blocks was lower at all depths than the cover recorded prior to this period This could bear evidence of the loss of live coral cover following the worldwide abnormal increases in sea temperature in 1998. The decrease was of particular significance at the depths of C.D.L.-1m and -3m, where increased sea temperatures must have had greater impacts on the corals. Comparing the results of the 19th and the 21st years, a marked increase in coverage was observed at the depths of C.D.L.-1m and -3m in the 21st year. The results also recorded the highest coverage at the depth of C.D.L.-12m between the 14th and 17th years. This phenomenon is attributed to the difference in the dominant coral species at each depth: Acropora (C.D.L.-1m), *Acropora* and *Pocillopora* (C.D.L.-3m), *Pocillopora* (C.D.L.-7m and -9m), and *Porites* (C.D.L.-12m). The year-on-year changes by depth therefore reflect the recovery processes of these corals. At shallower depths, the *Acropora* and *Pocillopora* species had suffered a reduction in coral cover under the increased temperatures, but showed signs of recovery in later years; while at deeper depths, the *Porites* species survived the period of augmented temperature and continued their growth.

Coral settlement and growth on Eco Blocks

Figure 3 and 4 illustrate the results of coral colony number and coral cover by depth and surface roughness. Graphs represent the mean value (n=3) of the data.

Changes in number of colonies

The number of colonies on the Eco Blocks had been on the rise for all levels of surface roughness at the depth of C.D.L.-2m for two years after block installation. The rougher surfaces demonstrated a greater effectiveness in terms of initial settlement of corals. After the third year, the number of colonies began to decrease on the surface with abrasions of 10mm deep, and it leveled off on the surface with abrasions of 5mm deep. However, on the surface with a roughness of 2mm deep, the number of colonies continued to increase before it plateau in the fifth year. In contrast, colonies on the control blocks showed a slow and gradual increase in number. At the depth of C.D.L.-5, the number of colonies had been largely on the rise for all levels of surface roughness until the fourth year. The greater effectiveness was observed for rougher surfaces as seen in the results from the depth of C.D.L.-2m. After the fourth year, the number of colonies showed a decline trend at all roughness, while the colonies on the control blocks again showed a slow but gradual increase for all surveyed years. At the depth of C.D.L.-8m, the number of colonies were also increasing for over three to four years after block installation but its relationship with surface roughness was not clearly observed.

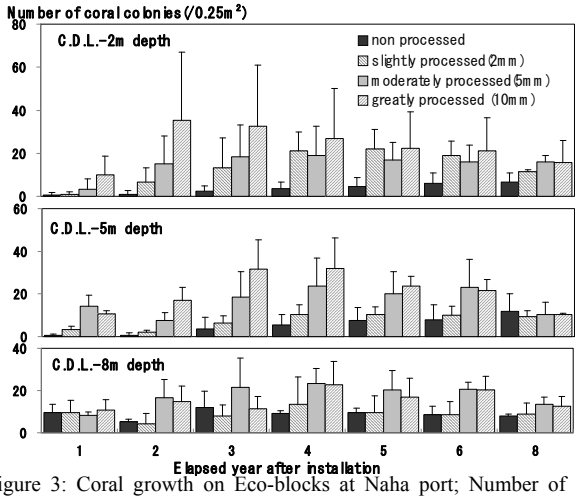

Figure 3: Coral growth on Eco-blocks at Naha port; Number of colonies. The blocks were installed in 1999. (Mean+SD: n=3)

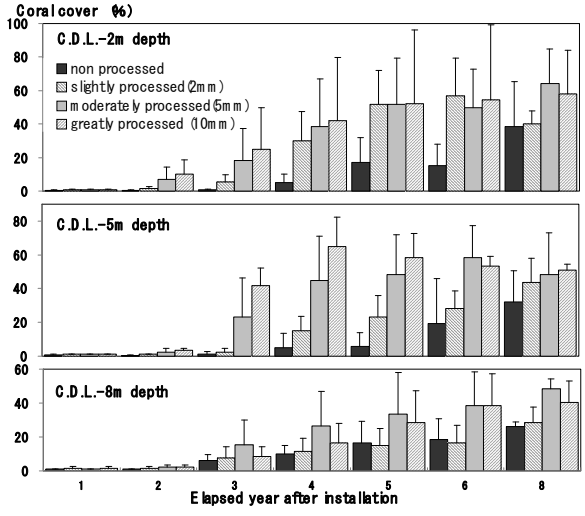

Figure 4: Coral growth on Eco-blocks at Naha port; Coral cover. The blocks were installed in 1999. (Mean+SD: n=3)

Changes in coral cover

At the depth of C.D.L.-2m, the coral cover on the blocks with abrasions of 10mm deep and 5mm deep showed a distinct increase in the third year. In this passage of years, the effects of surface roughness to

coral cover were apparent. After the fourth year, the coral cover on the surface with 2mm-deep abrasions also showed an accelerated increase, reaching closer to those on rougher surfaces towards the eighth year. In parallel, the number of colonies on the processed area showed a decrease, which is probably a result of spatial competition among corals during the colonization process, or the fusion of colonies among the same species. At the depth of C.D.L.-5m, the coral cover on the surfaces with abrasions of 10mm and 5mm hovered at moderate to high levels after the fourth year, ranging between 45% and 65%. On the surfaces with abrasions of 2mm and the control, the coverage for both was gradually increasing after the sixth year, almost rivaling each other by the eighth year. The results from the depth of C.D.L.-8m did not show as major an increase in cover as in shallower waters; however, rougher surfaces (abrasions of 5mm deep and 10mm deep) demonstrated a more rapid increase in coral cover than that on slightly processed surfaces (2mm deep) and the control.

Discussion

Coral settlement and growth on Eco Blocks

The data accumulated on coral settlement and growth processes can be expressed as a curve akin to a logistic curve (Yamamoto, et al, 2002). Taking into account the life cycle of corals, the growth process of corals can be classified into four stages as shown in Fig. 5; 1) recruit period– planula larvae settle on substrates, 2) post-settlement stage– attached planulae develop into polyps, 3) exponential growth stage – budding of polyps affords exponential increase in coral cover, and 4) stable-growth stage. We discuss the effects of uneven surface processing of Eco Blocks on coral settlement and growth at each stage.

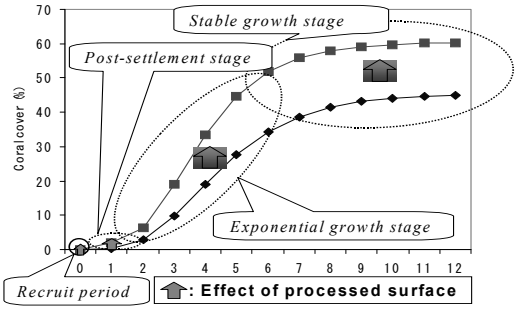

Figure 5: Schematic view of coral growth processes

Larval settlement stage (Recruit period)

Corals release eggs and sperm once in early summer. Fertilized eggs then become planula larvae and drift in surface waters for several days to weeks before attaching themselves to a stable substrate. It is known that the planulae seek out a surface suitable for them to attach to and grow into polyps, and that a top surface of a substrate is seldom sought (Babcock and Mundy 1996). The planula is about 1mm long. Given its tiny dimensions, the uneven processing on the block surface that creates angular sides, if of an appropriate depth, can benefit their settlement to a greater extent than flat surfaces. It is also reported that the roughness on the substrate surface can enhance the attachment of large sea weeds (Terawaki 1988; Watanuki et al. 1990). The reasoning behind this is considered to be the presence of the disturbed flow area and stagnant flow area that are created on the surface with slight abrasions. As such, there is a possibility that these two flow areas created on an unevenly processed surface can physically facilitate the attachment of planulae. This theory could explain the results we obtained in Naha Port, in which larval recruitment and number of coral colonies in the initial growth on the processed area exceeded those on the control.

Initial growth stage (Post-settlement stage)

There is no clear definition that differentiates the initial growth stage from the stable growth stage. However, it has been reported that the growth of newly settled polyps during the initial growth was slow, with higher mortality rates (Wilson and Harrison 2005). The reason behind this is due in part to the presence of predators or competitors in a coral reef ecosystem. Crown-of-thorns and *Drupella* are among the most famous predators, but young polyps are also affected by random grazing by sea urchins such as *Echinometra* and *Diadema* and fish such as parrotfish *Sparisoma viride* (Sanchez et al. 2004) and snail such as *Coralliophila abbreviata* (Williams and Miller 2006).

As these animals also feed on algae that compete with corals for space, some reports have cited that an increase in sea urchins like *Diadema* can result in an increase in coral colonies and coral cover (Macintyre et al, 2005); however, it should be considered that densities of corals, algae and predators dictate their relationships.

With such low chances of survival at this stage, the presence of an unevenly processed surface capable of offering a shelter to newly attached corals against predators, could physically aid in the improvement of survival rates. Also newly-installed structures, which are usually void of large sessile animals or plants that inhibit planula settlement and initial coral growth, could be one of the factors to improve coral settlement and growth.

Exponential growth stage and stable growth stage

Corals grow exponentially at this stage. Therefore, the increase in coral cover seems to depend on coral recruitment in the larval settlement stage and survival

rates during the initial growth stage. The results from the monitoring surveys on Eco Blocks in Naha Port also illustrate the growth with the initial increase in colony numbers and subsequent increase in coral cover. With the increase in coral cover, the number of colonies decreases. It has been reported that mature colonies can be detached or fragmented by stormy waves (Madin and Connolly 2006). Against such external forces, an uneven surface processing that affords a larger surface area and thereby a greater friction force, is expected to allow secure attachment for corals, and thus minimizes their detachment from the substrate.

Eco Block as a restoration technology

After the implementation of wave-dissipating blocks in 1986, the coverage of coral communities exceeded 50% in the eighth year and leveled off until the high temperature-induced bleaching brought about extensive damage to coral communities in 1998. The recovery process shown from 1998 until 2007 illustrates a slower growth of the corals at all depths except for C.D.L.-12m, compared to that before the bleaching.

It has also been reported that coral recovery on old wave-dissipating block, on which dead coral skeletons from the bleaching still remained, was slower than that on the new blocks (Ooka et al. 2006). The space within the coral skeleton serves as habitat for new larval recruits, but it also can be utilized as habitat by coral-predators including gastropods and sea urchins. In addition, some researchers have reported a reduction in larval recruitment after the bleaching events (Jinendradasa et al. 2000; Omori et al. 2001).

In other words, the decreased larval recruitment in the post-bleaching period, and the inhibition of initial larval settlement by mobile benthic predators are considered to be the major factors for the slow coral recovery on substrates after the bleaching.

Meanwhile, when the unevenly processed blocks were compared with the non-processed blocks in Naha Port, the processed blocks showed a significantly greater number of coral colonies. This could imply the possible effectiveness of the surface processing in enhancing the settlement of larvae in conditions where larval supply is poor.

Bachtiar (2000) reported a possibility of coral reef restoration using an artificial substrate. Fox (2005) reported her work in Indonesia's Komodo National Park where she placed artificial substrates among coral reefs having been destroyed by blast fishing and confirmed the steady settlement of *Acropora* species four to five years after the placement.

With all these findings and previous reports, we believe that the placement of artificial substrates with unevenly modified surfaces into the waters of coral reefs suffering degradation can facilitate coral recovery and thus aid in the restoration of coral communities.

Survival and growth of *Acropora spp.* in mid-water nursery and after transplantation at Phi Phi Islands, Andaman Sea, Thailand

L. Putchim[1], N. Thongtham[1], A. Hewett[2], H. Chansang[1]

1) Phuket Marine Biological Center, P.O.Box 60, Phuket 83000, Thailand
2) The Adventure Club Ltd. Part., Phi Phi Island, Krabi 81000, Thailand

Abstract. This study aims to determine the survival and growth rates of coral fragments in a mid-water nursery and after transplantation at Phi Phi Islands, the Andaman Sea. A total of 1,120 fragments of two dominant species, *Acropora grandis* and *A. muricata,* were used as seedlings. The average size of fragments was 4.6 cm (SD ± 1.2) and monitoring was conducted monthly. After 4 months in the nursery, survival of fragments was 95.8% and 94.8% for *A. grandis* and *A. muricata*, respectively. There was a significant difference ($p<0.05$) of growth rate in the nursery between *A. grandis* – 0.41 cm mo^{-1} (SD ± 0.21) and *A. muricata* – 0.23 cm mo^{-1} (SD ± 0.20). After 6 months in the nursery, coral fragments were transplanted to a nearby reef which had been destroyed by the Indian Ocean Tsunami in 2004. Survivorship of transplanted fragments after one year was 87.0% for *A. grandis* and 75.3% for *A. muricata*. Growth rates of transplants of *A. grandis* (0.28 cm mo^{-1}) and *A. muricata* (0.38 cm mo^{-1}) did not differ significantly. The relatively high survival suggests that these fast growing corals may be suitable for transplantation in the Andaman Sea area.

Key words: rehabilitation, coral nursery, coral transplantation.

Introduction

The mid-water coral nursery technique was developed in the Red Sea (Shafir et al. 2006) and has advantages in reducing impact to donor colonies, by removing small amounts of coral fragments only, and minimizing sediment smothering to corals in nursery (Shaish et al. 2008). We tested this technique, which has been shown to be successful in a turbid water environment (Putchim et al 2007) to rehabilitate a reef at Phi Phi Islands (Andaman Sea) that was damaged by the Indian Ocean Tsunami in 2004. Survival and growth of two *Acropora* spp. in both a mid-water nursery and after transplantation were studied.

Material and Methods

Study area

The study site was located in the northeast region of the Phi Phi Islands, Andaman Sea, Thailand (7°41.67′ N and 98°41.4597′ E, Fig. 1). A narrow reef with adjacent sandy substrate at approximately 5-18 m depth was chosen. Branching corals of genus *Acropora* especially *A. muricata* and A. *grandis* were dominant species. This reef is a popular diving site and was damaged by the Indian Ocean Tsunami in 2004. The environmental parameters of the area are as follow: annual salinity ranges from 30 to 32 ppt; transparency varies from 7-17 m Secchi depth; and sedimentation rate ranged from 31.2-58.3 $g.m^{-2}.d^{-1}$.

Nursery design

The mid-water nursery was set up at a depth of 12 m within 500 m of the transplantation site at the northeast of the island in May 2006 and corals were reared in the nursery for 4 months until September 2006 (Figure 2). The mid-water nursery was made of 16 modular structures, each consisting of 70 x 90 cm plastic mesh trays attached by cable-ties to rectangular 1.4 x 3.6 m frames made of 1.8 cm PVC pipe. The nursery was comprised of 2 PVC frames, at 1.5 m distance, creating a platform of 4.3 x 3.6 m. The platform was suspended at 6 m depth from four 46 cm mooring buoys which were connected to each other by ropes with small foam buoys sewn at 0.5-m interval. The mooring buoys were held in place by eight 20 kg cement sinkers, each secured to the substrate with 2 anchors.

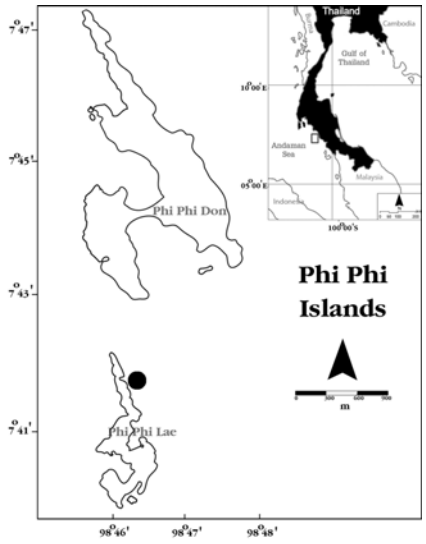

Figure 1: Study area in Thailand, showing the study site

Collecting fragments and transplanting in the nursery
Fragments of two dominant species at Phi Phi Islands, *A. grandis* and *A. muricata*, were collected from the vicinity of the nursery. The average size of the 1,120 fragments was 4.6 cm (SD ± 1.2). Each fragment was inserted into a plastic tube about 4 cm in length, which was attached to the tray mesh (70 pieces per tray). A total of 16 coral trays were fixed onto the PVC platform (Fig 3). Survival and growth were monitored every month for 4 months by recording the status of each fragment as dead, partially dead, bleaching, live, or missing. 24 fragments of *A. grandis* and 57 fragments of *A. muricata* were tagged and measured, by taking under-water photographs of fragment heights with a digital camera using a ruler for calibration.

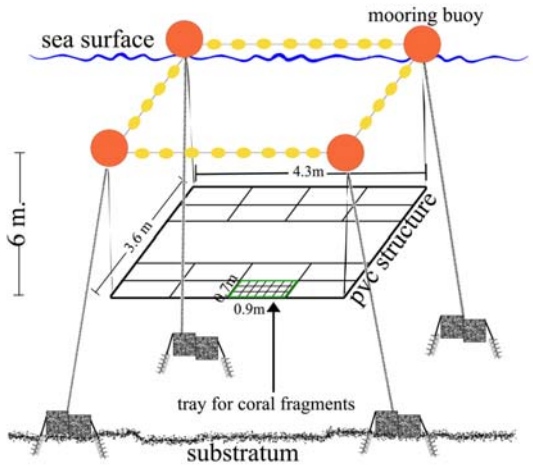

Figure 2: Diagram of floating nursery at the Phi Phi Islands

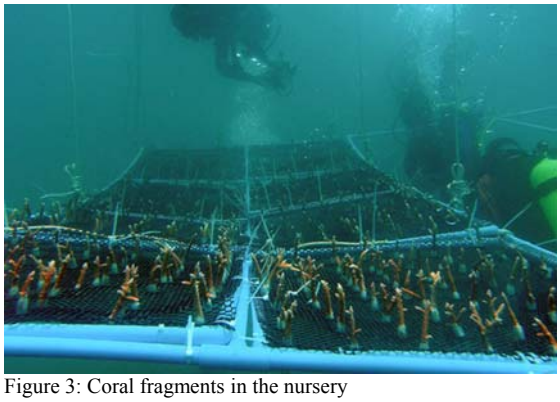

Figure 3: Coral fragments in the nursery

Transplanting to the degraded site
After 6 months in the nursery, the coral fragments were transplanted to a degraded site at 8-10 m depth in November 2006. The fragments were attached to substratum by fastening to metal bars with plastic cable-ties. Those metal bars were welded to a 1-m long metal frame with two legs at either end. Each frame comprised six 15cm long, 1.3 cm diameter metal bars and was secured directly to the substratum which was covered by dead coral rubble. A total of 116 fragments of *A. grandis* (23) and *A. muricata* (93) were transplanted and monitored for survivorship monthly. Growth was measured at beginning and the end (October 2007) of the study period. A subset of eight fragments of *A. grandis* and 18 fragments of *A. muricata* were tagged and measured.

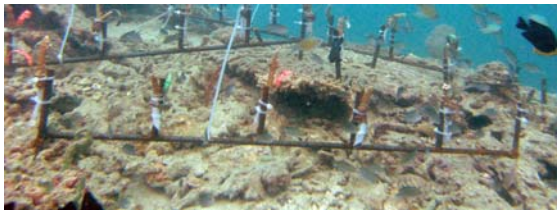

Figure 4: Transplantation method using metal bar attached to the substratum.

Data analysis
Measurement of fragments height was carried out by analyzing pictures taken from the field with Photoshop and Image-Tool software (Shaish et al. 2008). A Student's *t*-test was used to compare growth rates of the two species both in the nursery and after transplantation.

Results
Coral fragments of both species were kept in the mid-water nursery for 6 months, but growth and survivorship were monitored only for the first 4 months. Figure 5 shows the condition of *A. muricata* at the beginning and after one year of transplantation. Survivorship of *A. grandis* and *A. muricata* in the

Table 1: Survival and growth rates of *Acropora grandis* and *A. muricata* in the nursery and after transplantation. Mean and SD are shown for growth rates.

	Coral species	Survivorship			Growth		
		No.	months	%	No.	size (cm)	Growth rate (cm mo^{-1})
Nursery	*A. grandis*	210	0			4.4±0.7	
		192	4	95.8	24	6.1±1.2	0.41±0.21
	A. muricata	842	0			4.6±1.4	
		797	4	94.8	57	5.5±1.6	0.23±0.20
After transplantation	*A. grandis*	23	0			7.1±1.6	
		20	12	87.0	8	10.2±3.7	0.28±0.24
	A. muricata	93	0			5.7±1.9	
		70	12	75.3	18	9.9±3.6	0.38±0.31

nursery was 95.8% and 94.8% respectively after 4 months and growth rates were 0.41 cm.mo^{-1} and 0.23 cm.mo^{-1} respectively (Table 1). The growth rate of *A. grandis* was significantly higher than that of *A. muricata* (*t*-test, $p<0.05$).

Survivorship and growth rates of coral fragments of both species transplanted to the degraded reef area were monitored for 12 months. Survivorship of transplanted fragments was 87.0% for *A. grandis* and 75.3% for *A. muricata*. Growth rates were 0.28 cm.mo^{-1} for *A. grandis* and 0.38 cm.mo^{-1} for *A. muricata* (Table 1) and were not statistically different (*t*-test, $p>0.05$).

One year after transplanting, most of transplanted colonies still did not attach to the metal bars with only one out of 26 monitored colonies becoming partially self-attached (Fig. 6).

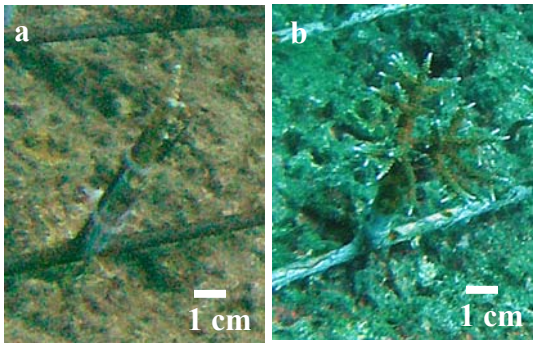

Figure 5: (a) An *Acropora muricata* transplant at the beginning of transplantation; (b) the same transplant one year after transplantation.

In August 2008, two years after transplantation, the site was also visited. About 50% of the transplanted colonies had grown to fill the 20-cm spaces in between the metal bars. However, some colonies were still at the initial transplanted size and a few colonies were missing or dead.

Figure 6: A transplanted colony partially self-attached to a metal bar after one year.

Discussion and Conclusion

Rearing of corals in mid-water nurseries is a relatively new technique (Shafir et al. 2006). The results from this study in the Andaman Sea and those of Shaish et al. (2008) from the Philippines indicate that the technique can be beneficial in areas other than the Red Sea (Shafir et al. 2006). The present study shows promise in an area with relatively high sedimentation (Putchim et al. 2007). In the Andaman Sea, we had to use larger initial fragments than those in the Red Sea because of higher turbidity and sedimentation. For example, small-sized (1 cm) *Pocillopora damicornis* fragments survived well in a mid-water nursery in the Red Sea (Shafir et al. 2006) but did not survive in turbid coastal waters of Cape Panwa, Phuket Island, Andaman Sea (Putchim 2007). Sedimentation rates at Cape Panwa varied from 200-500 g.m^{-2}.d^{-1} whereas those in the Red Sea varied from 1.8-8.4 g.m^{-2}.d^{-1} (Bongiorni 2001). In this study at Phi Phi Islands which has moderate sedimentation rates (ranging from 31.2 ± 2.7 g.m^{-2}.d^{-1} to 58.3 ± 1.6 g.m^{-2}.d^{-1}), the initial mean height for both species was 4.6 cm. This size appeared adequate to ensure survival.

This study showed high rates of survivorship in *A. grandis* and *A. muricata* in the nursery and after transplantation. The mean growth rate of *A. muricata* after transplantation (0.38 cm.mo^{-1}) was similar to that of *A. muricata* in transplantation at Cape Panwa, Phuket (0.3 ± 0.3 cm.mo^{-1}) (Yucharoen et al. 2008)

and growth rate in Okinawa (3.5 $cm.yr^{-1}$) (Okubo et al. 2005). Whereas the growth rates of *A. muricata* in the natural environment of the Andaman Sea showed seasonal variation ranging from 0.3 $cm.mo^{-1}$ during the SW monsoon to 0.9 $cm.mo^{-1}$ during the NE monsoon seasons (Charuchinda and Hylleberg 1984; Chansang et al. 1992). Growth of *A. muricata* in our study was less than that obtained using the same technique in the Philippines (0.8 $cm.mo^{-1}$) (Shaish et al. 2008). The practice of using metal bars for fixing transplanted fragments to substratum should be reviewed as growth of live tissue over the metal was very limited and adding foreign objects into the reef environment should not be encouraged. However, the metal frames helped to secure transplanted colonies until they were large enough to withstand the surrounding water movement. After 2 years, the frames were not very visible as transplanted colonies had grown to cover the frames.

In conclusion, fragments of *A. muricata* and *A. grandis* had high survivorship both in nursery and after transplantation, thus it is recommended that these coral species are suitable for nursery and transplantation in the Andaman Sea.

Acknowledgement

This study was conducted under the programme **"**Developing ubiquitous practices for restoration of Indo-Pacific reefs"**,** REEFRES, supported by European Commission. The assistance of Prof. Baruch Rinkevich and his team from Israel's National Institute of Oceanography in conducting the study is highly appreciated. Our thanks also go to volunteer divers who worked in setting up and monitoring the floating nursery. We thank the staff of Marine Biology and Ecology Unit, Phuket Marine Biological Center (PMBC), for field assistance.

Coral transplants as rubble stabilizers: a technique to rehabilitate damaged reefs

P.T. Rojas Jr.[1], L.J. Raymundo[1,2*], R.L. Myers[1]

1) University of Guam Marine Laboratory, UOG Station, Mangilao, Guam 96923

Abstract. Developing practical techniques to mitigate the effects of coastal development, ship groundings and destructive fishing has challenged reef managers for 30 yr. Coral communities reduced to rubble do not support recruits due to their instability; such areas have slim chances of recovering naturally. We relocated "corals of opportunity" to a 50-year-old rubble bed and tested the efficacy of using two species of corals with contrasting morphologies as rubble consolidators. We hypothesized that *Porites rus,* which forms upright columns and extensive basal plates, would be a superior consolidator to *Porites cylindrica,* which has a dendritic growth form without basal plates. After 18 months, growth and survival varied significantly between species. The majority of *P. rus* transplants survived (93.3%), while only 23.3% *P. cylindrica* transplants did. Mean basal growth was 0.8 mm mo^{-1} for *P. rus* and 0.07 mm mo^{-1} for *P. cylindrica,* with *P. rus* overgrowing rubble within 6 mo. The plate-forming morphology enhanced survival by stabilizing fragments as they grew. In contrast, none of the *P. cylindrica* transplants consolidated onto rubble during the course of our study.

Key words: rehabilitation, *Porites,* rubble stabilization, Guam.

Introduction

Guam reefs have traditionally been heavily used for food and recreation (Amesbury and Myers 1982; Zeller et al. 2006) and fish stocks have declined steadily over the past 50 yr. The Guam Visitors Bureau reported a record high of 1 million Asian tourists in 2004, a dramatic increase over past years despite economic setbacks (GVB 2004). Physical damage to reef structure from water sports is associated with premier tourist destinations (Hawkins and Roberts 1993; Rouphael and Inglis 2001; Burdick et al. 2008), increasing coral mortality and loss of reef structure (Edwards and Clark 1998; Bowden-Kerby 2003). Compounded by chronic nutrient inputs, sedimentation and pollution, and acute outbreaks of the Crown-of-Thorns starfish (Birkeland and Lucas 1990), recovery of Guam reefs has been slow to non-existent. A further complication is low coral recruitment (0.14 recruits/15-cm^2; Birkeland et al. 1981, 0.002 recruits/15-cm^2; Birkeland 1997, 0.013 recruits/15-cm^2; Minton and Lundgren 2006). The reasons for this are unclear and therefore difficult to mitigate. If Guam reefs are self-seeding due to minimal larval flow between islands, declines in coral cover will be self-perpetuating (Porter et al. 2005).

Restoration ecology explores approaches to mitigate damage to ecosystems, promote recovery, and reestablish specific attributes and function (Rinkevich 2005). Techniques currently employed range from coral gardening and transplantation to deploying artificial structures for recruitment substrate and habitat. In Guam, coral transplantation has been conducted since the late 1970s with various objectives, which have included: reestablishing coral communities in thermal effluent areas (Birkeland et al. 1979), preserving rare coral species (Plucer-Rosario and Randall 1987), translocating corals due to underwater construction and ship groundings (Naughton and Jokiel 2001), and mitigating coral loss from fiber optic landing development (Kolinski 2002). However, the challenging issue of persistent rubble fields from physically destructive events has been largely ignored. As Guam reefs will be subjected to increasing coastal and military development, continuous boat activity, and periodic typhoon surge, this problem requires urgent attention.

Despite the innate ability of corals to fragment, survival depends on attachment to stable substrate (Bothwell 1982). Corals can recover from natural calamities such as storms, but chronic fragmentation by human activity creates rubble fields which fail to consolidate because recruits do not survive. Practical approaches to rehabilitate rubble and facilitate coral reestablishment are few. Fox et al. (2005) and

Raymundo et al. (2007) found high transplant survival and recruitment on rubble stabilized by combinations of plastic mesh, rock piles and cement slabs.

This investigation tested the use of coral fragments to consolidate rubble while simultaneously relocating corals from a marginal habitat scheduled for dredging. These 'corals of opportunity' (Edwards and Gomez 2007) were a mixed community of *Porites rus* and *Porites cylindrica*. We compared the rubble stabilizing ability of plate-forming *P. rus* with the upright branching *P. cylindrica.* We predicted that *P. rus* would be a superior species to consolidate underlying rubble than *P. cylindrica* due to its morphology and rapid growth rate (Veron 2000).

Materials and Methods

Study site

The experiment was conducted on Sumay Mound, a nearshore seamount rising from 30 m to 15 m depth, 1 km south of the Apra Harbor inner channel dredge site. Approximately 20% of this reef was dominated by rubble from anchor damage in the 1950s. Recovery, to date, has been insignificant. Further, the rubble bed is seasonally dominated by the foliose macroalga *Padina sanctae-crucis* such that live hard coral cover constituted only 15% of the substrate (Fig. 1). The persistent rubble, protection from typhoon surge and proximity to the source site were attributes favorable for our recipient site.

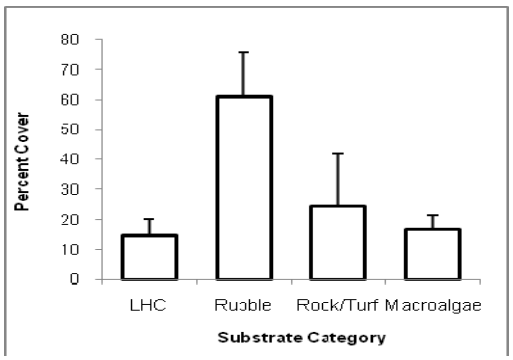

Figure 1: Benthic composition within the rehabilitation site on Sumay mound, showing a dominance of coral rubble.

Coral translocation and establishment

Fifteen colonies each of *P. rus* and *P. cylindrica* were transported from the channel to Sumay Mound and allowed to acclimate for 12 weeks. Three 14 m^2 areas within the rubble field were manually cleared of macroalgae. Donor colonies were then fragmented into sizes of three to four branches and cemented upright to three rubble pieces using Z-Spar Marine Epoxy®. This fragment size provided refuge from size-specific mortality (Hughes and Jackson 1985; Harriot and Fisk 1988) and the rubble provided weight and stability. Twenty such fragments (10 per species) were positioned in rows within each plot, with the two species alternating within each row. Transplant performance was monitored at regular intervals for 18 mo. Weeding of *Padina sanctae-crucis* was undertaken as necessary and fragments that had become overturned or detached were repositioned and re-epoxied. Yap et al. (1992) found that corals transplanted during warm months survived and grew less than those transplanted in cooler months. Therefore, we monitored temperature using Stow-away Tidbits (Onset Corp.®).

Transplant performance was characterized per species as timing of basal attachment to substrate, basal growth (mm mo^{-1}), disease signs, tissue loss or compromised health (bleaching, algal overgrowth), recovery from partial mortality, and full mortality. Basal growth was expressed as mean maximum basal width in millimeters. Disease prevalence was calculated as the number of fragments showing disease / total fragment number * 100. As differences between plots were insignificant, data for each species were pooled for analysis using unpaired *t*-tests.

Results

Porites rus consistently demonstrated better overall performance than *P. cylindrica,* by having low partial mortality, high survival, less disease and high consolidation rates via rapid basal growth. Per species mean responses are summarized in Table 1.

Table 1: Summary of transplant performance, mean ± SD.

Performance parameter at 18 mo	Species	
	P. rus	*P. cylindrica*
% survival	93.3±0.05	23.3±25.1
% with partial mortality over 18 mo period	67.0±20.8	96.6±5.7
% with tissue regrowth at 18 mo	56.6±15.7	0
Mean basal width (mm)	62.8±6.1	37.4±6.7
Total basal growth (T_{final}-$T_{initial}$)	13.5±0.6	-1.2±0.20

Basal consolidation and growth

It took approximately three months for coral tissue to begin to overgrow the epoxy and rubble pieces. At this time, 74% of *P. rus* transplants showed initial cementation onto substrate, while only 27% of *P. cylindrica* transplants showed this response. By the end of our monitoring period, 10% of *P. cylindrica* fragments had attached to underlying rubble, as opposed to 62% of *P. rus* fragments. Basal growth rate averaged 0.75 mm mo^{-1} for *P. rus*, and 0.07 mm mo^{-1} for *P. cylindrica*, for the months when there was positive growth (t=8.51; p<0.001).

Partial mortality

Partial mortality involved tissue loss which usually began at the fragment base and progressed upward. Recovery involved tissue re-sheeting over dead skeleton. When this did not occur, skeleton was rapidly colonized by algae, resulting in additional tissue loss over time. While it was difficult to determine the causes of mortality, bleaching and coral diseases (ulcerative white spots and white syndrome; Raymundo et al. 2003; Willis et al. 2004) were observed periodically. Seasonal accumulation of *Padina* around the base of fragments resulted in bleaching of underlying tissue; this was the most common cause of tissue bleaching and loss. An average of 23% of *P. rus* transplants incurred partial mortality within the first three months and by the end of the study period, 67% had exhibited some tissue loss but 57% of these showed some tissue resheeting over the dead skeleton (Table 1). Partial mortality for *P. cylindrica* on the other hand, increased rapidly from 27% at 3 mo, to 97% by 18 mo (*t*-test of mean mortality between species; p=0.0164). Thus, whereas 57% of *P. rus* transplants that lost tissue showed recovery, *P. cylindrica* fragments with partial mortality died.

Full mortality

Overall, *P. rus* survived better to 18 mo than did *P. cylindrica* (Table 1, Fig. 2; *t*-test p=0.041). Sources of mortality were the same as those mentioned above, though while *P. rus* appeared to recover more frequently, *P. cylindrica* transplants more often showed a general decline in health over time with accompanying tissue loss and algal overgrowth. Further, because they failed to consolidate around the base of the fragment, overturning, detachment and subsequent abrasion and tissue loss were also causes of mortality.

Coral disease

Ulcerative white spots disease affected *P. cylindrica* much more than *P. rus* (*t*-test p=0.014), and most severely within the first three months after translocation. UWS prevalence reached a high of 23% at 3 mo in *P. cylindrica* transplants, though infected fragments showed subsequent recovery and none died of the disease. UWS was observed on *P. rus* at two census visits, October 2006 and March 2007, and all fragments recovered by the next census. What appeared to be putative white syndrome lesions appeared on several *P. cylindrica* fragments, though these lesions usually became fouled with algae by subsequent census visits and did not appear to progress. There was no evidence of a link between prevalence of either disease and seasonal warming seawater temperature.

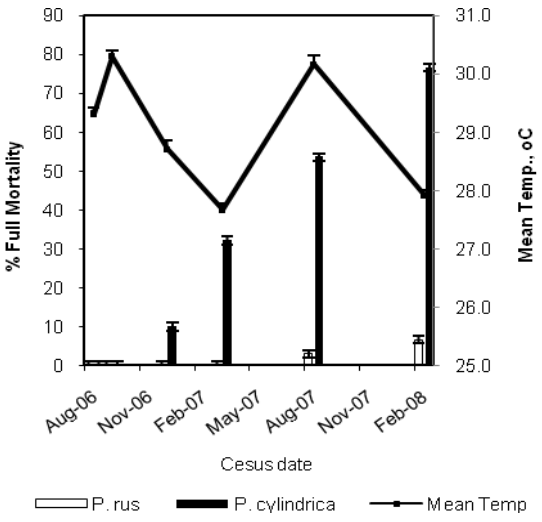

Figure 2: Cumulative mortality over time in two species of transplants, plotted against mean weekly water temperature. N=20 fragments per plot; mean ±SD

Temperature seasonality effects

Water temperature showed a seasonal trend; highest temperatures were recorded during August (31.2°C) and coolest temperatures occurred in January-February (27.5°C; Fig. 2). However, although bleaching was recorded at other sites around Guam during the warm season, no bleaching was observed in our transplanted population. Further, our data suggested no correlation between warm water and any of the performance parameters we measured.

Discussion

Our results showed that live coral transplants can stabilize rubble in low-energy environments. The morphology of our two closely-related species affected their ability to consolidate rubble, which was key to their survival and establishment. *P. rus* was superior in overall performance, demonstrating low partial and full mortality, more frequent recovery, less susceptibility to disease, and greater basal growth and consolidation compared to *P. cylindrica* (Fig. 3). Yap et al. (1998) noticed a similar response; *P. cylindrica* fragments showed significantly more partial or full mortality at one year post-transplant than other test species. However, not all of our success measures can be attributed to morphology alone, suggesting that *P. rus* may have greater acclimatization capability.

The growth rates we observed were lower than rates for other species reported in the literature. Raymundo (2001) reported an increase in fragment surface area of 5 cm^2 wk^{-1} in *Porites attenuata,* which is closely related to *P. cylindrica.* Similar rates were observed in *Acropora hyacinthus* transplants by Yap et al. (1992; 6.9-117 cm^2 mo^{-1}) and *Pocillopora damicornis* (~2.65 mm mo^{-1} linear growth; Birkeland 1979). However, we report here only basal extension

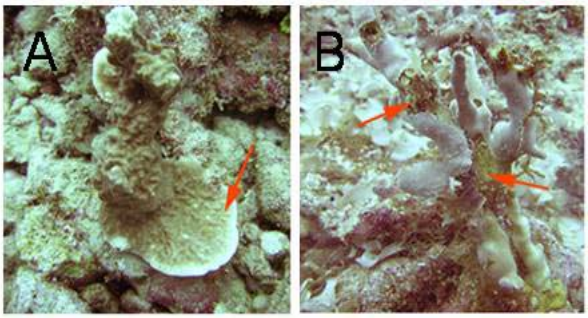

Figure 3: Transplants of (A) *P. rus* and (B) *P. cylindrica* at 18 mo. *P. rus* shows basal plate formation (arrow) and consolidation on rubble; *P. cylindrica* shows tissue loss and algal overgrowth (arrows).

as the relevant growth parameter for our study, as consolidation rate was the metric of concern. As basal plates are generally circular to ovoid in area, this translates into substantial surface area. For instance, mean maximum basal width for *P. rus* transplants at 18 mo was 7.3 cm. Using the formula for surface area of a circle, this would provide roughly 44 cm^2 of basal skeleton cemented onto the underlying rubble. An increase in maximum width by 1 cm would translate into an increase in surface area of 12 cm^2. Although these figures are rough estimates, they provide some idea of the rate at which *P. rus* would cover rubble substrate over time.

Mortality was higher in *P. cylindrica* and most prevalent during seasonal abundances in *Padina* spp. The alga overgrew the base of most fragments. Direct contact of corals with macroalgae is energetically costly (McCook et al. 2001), and diverts resources for growth toward tissue repair (Lirman 2001). Although both species were equally susceptible to algal overgrowth, *P. rus* more often recovered after initial contact with algae.

In Guam, *P. rus* dominates many coral communities, often occupying ~ 80% of the substrate (L. Raymundo, pers. obs.). This species demonstrates several traits which contribute to its dominance: an ability to rapidly co-opt space, outcompete other species (such as *P. cylindrica;* Caballes 2006), low susceptibility to disease (Raymundo et al. 2005). Holbrook et al. (2002) also noted that *P. rus* provides superior fish habitat to massive *Porites* species. All of these traits point to its suitability in rehabilitation efforts. However, it is important to bear in mind that the establishment of single-species stands should not be a goal of rehabilitation. Hardy, plate-forming species may be suitable for initial stabilization efforts, but other species should be introduced later to increase species and structural diversity.

Stabilized coral rubble provides a suitable substratum for recruitment and for asexually-produced fragments (Bothwell 1982; Fox et al. 2005). Raymundo et al. (2007) noted higher recruit survival on stabilized, rather than loose, rubble and recruits then further consolidated rubble as they grew. Stabilizing rubble also eliminates further damage to the reef, as when unconsolidated rubble shifts during storms (Clark and Edwards 1995; Fox et al. 2003). Finally, as rubble is replaced by live hard coral, macroalgal abundance may decline. This effect is particularly visible during periods of seasonal algal abundance (Gleason 1999).

Ulcerative White Spots (UWS) was first described as affecting the genus *Porites*, but has recently been observed on several other genera (Raymundo et al. 2005; Kaczmarsky 2006). The pattern of occurrence we observed suggested a link with fragment stress rather than seasonal temperature trends; transplanted fragments may have been stressed, and their immuno-defense capacity compromised, by the transplantation process. A similar pattern was observed in fragments of *P. attenuata* transplanted to a site with poor water quality in the Philippines, when the disease was first observed and described (Raymundo 2003). Disease is a potentially devastating source of mortality for transplants, and transplantation a potential source of disease introduction. To date, these issues remain untested but suggest a line of research that could improve transplant survival and be utilized to improve best practices for rehabilitation efforts.

Persistent rubble fields remain a challenge for restoration and are often ignored in favor of efforts which may result in higher survival. However, destructive fishing and boat groundings continue to create patches of "dead space" in reef communities. In the Philippines, patches created by destructive fishing practices banned 20 or 30 years prior persist with negligible coral growth (Raymundo pers. obs. and fisher interviews). Thirty years ago, Alcala and Gomez (1979) predicted dynamite-blasted reefs would take 50 yr to recover 50% of their original coral cover; Riegl and Luke (1998) increased the predicted regeneration time to several hundred years. Clearly, persistent rubble is an issue increasingly difficult to ignore. However, this source of damage frequently occurs at a scale at which many rehabilitation efforts currently operate (10^{-2} to 10^{-1} ha; Edwards and Gomez 2007). Therefore, efforts to develop methods to encourage regeneration will likely result in success.

Acknowledgements

This project was funded by the US Navy and the Coral Reef Initiative of Guam. Field assistance from C. Caballes, M. Defley, G. Grimm, J Miller, and C Bassler is greatly appreciated. Discussion with the Raymundo lab group improved this paper greatly. Finally, thanks to Haru, Pablo III and Maria Oceana.

Abstract. As part of a mitigation measure associated with the construction of a Liquefied Natural Gas plant, four large coral transplantations were carried out in Yemen between January and October 2007. Around 1,500 selected coral colonies were removed from areas to be impacted, transported and cemented in new sites. Transplanted colonies belong to 36 species and 25 genera. Among these, 140 large *Porites* spp. weighing from 200 kg up to 4 tonnes, were moved using new transplantation techniques. Growth, *in situ* mortality and health of the transplants were monitored over one year using photo quadrats, close-up pictures and linear growth measurements. Overall, survival of corals one year after transplantation was 91%. Most losses of transplants were apparently due to sedimentation of fine particles in the transplanted areas, fish predation, fisher activity and swell effects. Evidence of coral growth after transplantation was observed, especially in *Acropora* and *Porites* species, and on some faviids. The transplantation results demonstrate the capacity of corals to adapt to a new environment, in favorable conditions. They show that carefully designed coral reef rehabilitation strategies can be part of industrial development processes, whenever necessary.

Key words: coral transplantation, reef restoration, mitigation measures.

Introduction

The Yemen Liquefied Natural Gas (YLNG) project is a $5 billion project to build a pipeline and a liquefaction plant to process and ship natural gas from Yemen to the world markets. In the plant the gas is compressed and liquefied at minus 160°C and transported via sea tankers. YLNG's environmental approach is: first to eliminate or mitigate impacts by redesign when this is possible. If elimination or mitigation is not effective or possible, YLNG policy is to compensate for impacts, and to provide investment to promote sustainable improvement in marine environmental conditions, and monitoring of the marine environment to ensure that these measures are effective. Creocean carried out an Environmental Baseline Study (EBS) in 1997 and 2005. Up to that time, knowledge of corals in the region was limited to a few published references (Sheppard et al. 1992; Kemp and Benzoni 1999; Kemp and Benzoni 2000; Benzoni et al. 2003). The EBS showed that Bal Haf cape where the LNG plant is being constructed was characterized by a high coverage of diverse corals, abundant and diversified fish, and highly three-dimensional coral communities. As part of the mitigation measures, a coral transplantation was proposed to save coral colonies from destruction on sites where the marine works would take place.

Three localised areas with dense coral communities will be impacted by the construction works (Fig. 1). On the North side: 1) the Intake area where an intake water cooling pipeline will be placed to pump deep water, 2) the Jetty area where a loading jetty will be built to receive tankers, and 3) the Golf area, where a shoreline protection with concrete blocks is required. On the South side, one area will be impacted: the Outfall site where a pipeline is to be placed to discharge warm seawater after it has been used for cooling during the gas liquefaction process.

Different sites were chosen to receive the transplanted corals (Fig.1). Selected sites met the following criteria: they were close to the original sites but out of the impacts of the plant construction (the selected sites were from 100 to 1100 m away from the donor sites), and were characterized by similar depth, hydrodynamic and water quality conditions.

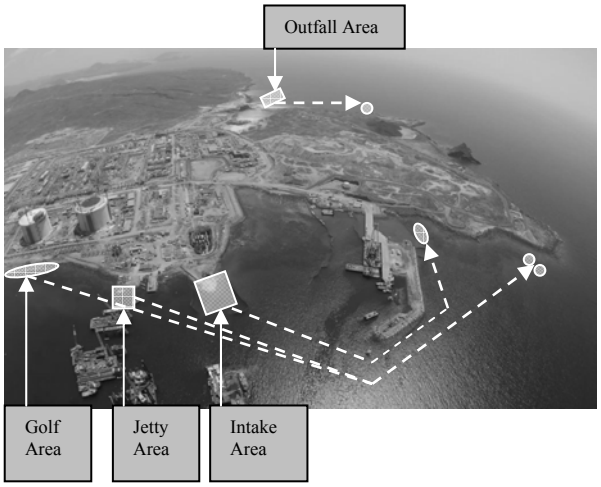

Figure 1: Aerial view showing the donor and the receiving sites.

A study of the coral communities on the donor sites revealed domination by the branching *Stylophora* with presence of large massive *Porites lutea* and *P. lobata*, and different faviids, especially *Platygyra daedalea* and *Favites* spp. A few tabular *Acropora* were also found. Because these areas were too large to be integrally transplanted and to increase the chances of coral survival, it was decided *a priori* to transplant selectively the largest colonies, the rare or uncommon species, the slow growing species, and only the colonies in good health. Edwards and Clark (1998) argued that there has been too much focus on transplanting fast-growing branching corals instead of slowly recruiting massive species, which generally survive transplantation well but often recruit slowly.

Material and Methods

The variety of colony shape and size among the transplanted corals required different methodologies of collection, transport and attachment. The small to medium-sized colonies (40–60 cm diameter) were removed using hammer and chisel and placed in pierced plastic baskets underwater. The baskets were loaded on a boat and directly transported to their final location (Fig. 2). They were protected from the sun and wind by a plastic cover and regularly splashed with fresh seawater. The medium to large-sized colonies (0.6–4 m diameter) were removed using a crowbar. Those colonies ≤1 m diameter were placed in a large steel basket (2 m^2 [base] x 100 cm [high]) directly underwater, which could be raised to the surface with lifting balloons and towed under the surface by boat. The large *Porites* colonies (1–4 m diameter and up to 4 tonnes) were drilled to a 20 cm depth in order to fix with epoxy resin one or two (12 or 18 mm) stainless steel screws into the skeleton, which could be attached to a lifting balloon (Fig.2). Each of these colonies were then lifted to the surface and slowly towed by boat to the transplantation site.

All the corals colonies were cemented at their final location to avoid damage by swell or fish predation. Epoxy was chosen for the fragile colonies such as branching *Acropora* species. It took around half an hour for the cement bond to become strong and a few hours to be totally hard.

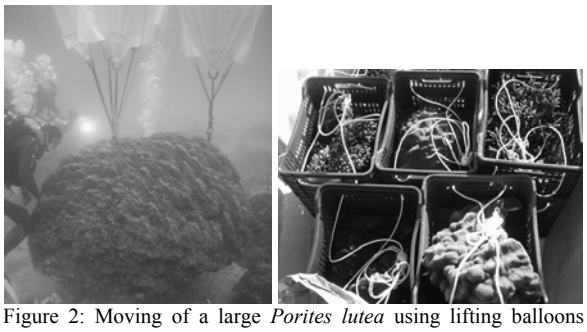

Figure 2: Moving of a large *Porites lutea* using lifting balloons (left), transport of small colonies in baskets out of water (right).

A monitoring program was set up to survey the different transplantation sites and to measure the adaptation of corals to their new environments. Every four to six months (2007: January, May, October; 2008: February, June) a digital image mosaic was taken of each entire site, after installing a grid. Survival and health (occurrences of diseases or damage) were recorded for each colony.

Close-up pictures and measurements using large calipers were used to survey the health of a dozen selected colonies per site, with quadrats being used to follow the growth of 10 tabular *Acropora*, 15 branched *Acropora*, 17 massive *Favites* and 24 *Porites lutea*. Plastic collars fixed to the colonies at the beginning of the monitoring were used as references for diameter, radial, or branch extension measures. Stainless steel cables were also installed on the surface of massive *Porites* to monitor their growth by coral tissue extension on the cable.

Results

1,495 coral colonies belonging to 11 families (Table 1), 25 genera and 36 species were removed from sites to be impacted and transported to new areas safe from the effects of the construction works. The taxonomic composition of the transplants (Table 1) was dominated by faviids with a large number of *Platygyra daedalea* and different species of *Favites*. A lot of Poritidae were translocated as well, with a special care taken in the case of 140 particularly large colonies (1–4m in diameter), weighing from 200 kg up to 4 tonnes .

Table 1: Number of transplanted colonies per scleractinian family and relative percentage

FAMILIES	NUMBER	%
Acroporidae	113	8.0
Agariciidae	71	5.0
Dendrophylliidae	7	0.5
Faviidae	750	50.0
Fungiidae	10	0.5
Mussidae	17	1.0
Oculinidae	12	0.5
Pocilloporidae	102	7.0
Poritidae	376	25.0
Psammocoridae	7	0.5
Siderastreidae	30	2.0
TOTAL	**1,495**	**100.0**

Fourteen months after the first transplantation operation in January 2007, 91% of the transplants were alive and healthy. The survivorship for each operation is shown in Table 2.

Table 2: Survivorship rate (%) of the transplantations depending on the duration of survival.

Area	Total (n)	Duration of survival (month)			
		3 (%)	5 (%)	10 (%)	14 (%)
Intake	608	99	-	96	94
Jetty	400	-	89	82	
Golf	79	-	78	74	
Outfall	408	-	100		

From the first monitoring after transplantation, there was some evidence of growth of the corals. Growth was observed at the base of the colonies where the living tissue overgrew the cement, the epoxy or the substrate directly. Colonies of the genus *Acropora* showed the most rapid growth, especially for the tabular colonies, with an average diameter extension of 1 cm mo^{-1} (± 0.4 cm).

Growth was also visible on the large *Porites lutea* on which stainless steel cables were placed. These were quickly covered by living tissue. A few samples were collected and analysed by tomography to determine the rate of growth of these corals.

Various types of damage occurred to corals after transplantation. An invasive red sponge (*Clathria* sp.) attacked corals at all sites, especially massive *Porites*. Its fast expansion induced considerable localised damage at transplanted sites, killing the coral by its growth over the living coral tissue. This phenomenon has also been recorded in other areas of the Gulf of Aden by Benzoni et al. (2008). Infestation by pyrgomatid barnacles was also recorded especially on *Porites* colonies and seemed to be seasonal and may possibly have been linked to the sedimentation at the sites. It was observed as well on non-transplanted corals. Fishermen caused additional damage. Swell and current induced coral damage occurred in July and August during the monsoon season. The use of cement with an adjuvant to keep it compact underwater was successful for most of the corals. Only three small colonies became detached after one year, but 17 out of the 140 large *Porites* were moved by the strong swell at the most exposed site (Fig.1, close to the cape). Rubble, sand and gravel transported by swell waves covered some of the branching colonies.

Fish were responsible for some coral damage, during the attachment phase. The large wrasse *Coris formosa* turned over the corals to eat boring shellfish living inside the coral skeleton and revealed by the collection process. Damage of *Porites* by the giant hogfish *Bodianus macrognathos* was also observed. Most of the loss transplants, especially on one of the areas where a large part of the transplanted corals belong to the Acroporidae (*Montipora* sp*.)* and the Agariciidae (*Pavona cactus)* were due to fish predation. Parrotfish and triggerfish scraped and broke parts of the coral colonies during feeding or nest-building respectively. This damage occurred to both natural colonies as well as the transplants, but the fish appeared more attracted by stressed corals than by healthy ones.

Finally, sediment deposits, which formed on the coral colonies, induced necrosis on top of massive corals such as *Platygyra daedalea* and *Favites* spp. in the transplant area closest to the plant construction works.

Discussion

The use of a screws drilled directly into the coral skeleton to fix to lifting balloons was an innovative technique to transport large corals. It allowed corals to be protected from damage during the collection and the transport phases (for example, abrasion of the living tissue by lifting belts usually used to move large corals). Moreover, it allowed the corals to remain underwater during translocation and allowed them to be positioned precisely on the receiving reef. No published references were available to compare the success of this technique because it is the first time such large corals have been successfully moved. Only references on the transplantation of small colonies (10–20cm) were found (Clark and Edwards 1995; Alcala et al. 1982; Plucer-Rosario et al. 1987; Yap et al. 1992) and these workers all used plastic baskets for underwater transports. All reported the same problem: considerable loss of transplants from higher energy sites, whatever methods of attachment. Following these results, we decided to cement all the transplants, even the heavy colonies (up to 1 tonne) and we only had loss due to swell at the most exposed site. This points out that the location of a relocation site is one of the most important variables in a transplantation operation.

The differences in survivorship between our different operations (from 74% to 94% over one year) are most likely due to effects of the monsoon. During the summer monsoon, extreme oceanographic conditions occur, with strong swell, current and wind, and an upwelling carrying cold water at around 17°C (Sheppard et al. 1992). We conclude that corals which were removed and transplanted just before the monsoon season did not have enough time to recover and adapt to their new environment before they faced adverse sea conditions. Indeed, the transplantation process, even if it is done well, is likely to be stressful for corals (Clark and Edwards 1995). The transplants need time to recover to be able to resist new stress. This may be why they seemed to be susceptible to predators and diverse attacks such as fish, red sponge or pyrgomatids. Survival in this study appeared relatively high compared to previous studies. For example, Alcala et al. (1982) obtained 40% survival of transplants after one year, Auberson (1982) 70%, but 20 to 50% on high-energy shallow sites, and Clark and Edwards (1995) 75% survival. This was probably partly due to the focus on larger, massive and sub-massive species in this project.

To contend with fish predation, we adapted our methodology, for example attaching the corals directly after their removal. Fish may be more attracted by stressed corals, perhaps due to the increase in the mucus production. The selection of corals in good health before transplantation is very important to limit these attacks.

To conclude, the 91% survival after more than one year is encouraging but other surveys are needed to complete these data. We can determine the best period of the year to move corals, depending on the season and the weather conditions: for Yemen waters it seems to be during the months following the monsoon. According to other authors, the species that better support the transplantation seem to be the massive ones such as the Poritidae and the Faviidae. The best way to move corals depends on the species, the size and the distance they need to be translocated. Large colonies can be towed underwater by boat and small ones transported out of water in pierced plastic baskets.

These operations show that it is possible to do something to save part of the reef when a construction work is necessary. It is also possible to use these transplantation techniques during the building of industrial plants, hotels, harbor extension, or any construction that will damage part of the reef for coastal development. The cost of mitigation appears relatively modest. As an example, the cost of this operation represents less than 1% of the total amount of the plant construction.

Acknowledgement

The authors wish to thank Yemen LNG for making this operation possible, F. Benzoni for her help, suggestions and knowledge of the area, M. Pichon for his help, suggestions and knowledge, helpers and professional divers from Yemen LNG for their help and observations on site.

Transplantation of *Porites lutea* to rehabilitate degraded coral reef at Maiton Island, Phuket, Thailand

N. Thongtham, H. Chansang

Phuket Marine Biological Center, P.O. Box 60, Phuket 83000, Thailand

Abstract. This study compared the growth and survival of different sized transplants of *Porites lutea* at Maiton Island, Thailand. Fragments in three different sizes, 5.0 x 5.0 cm (large), 3.5 x 3.5 cm (medium) and 2.5 x 2.5 cm (small), were detached from intact coral colonies. Unattached coral colonies in each size category from the site were also transplanted for comparison. The fragments and unattached colonies were cemented on concrete blocks. Medium-size fragments and colonies showed high survivorship whereas small-size fragments and unattached colonies showed low survivorship. Growth was measured as increase in colony plan area and increase in height. Area of transplants increased exponentially and the growth constant of small-size colonies was significantly higher than that of large-size colonies (S-N-K, p = 0.021). Rates of height increase were significantly different among all sizes for fragments (with smaller fragments performing more poorly) whereas there was no difference in this parameter among colonies. Medium-size fragments appeared the appropriate size for transplantation as they showed the highest survival. It is also recommended that all sizes of loose colonies should be used for transplantation as attachment increases their chance of survival, which assists natural recovery.

Key words: *Porites lutea*, coral transplantation, coral rehabilitation.

Introduction

For decades, coral reefs in Thailand have suffered from degradation as a result of both natural and anthropogenic disturbances including coastal development, sedimentation, destructive fishing and tourism-related activities. Concerned institutions and organizations from both the government and the private sectors have initiated coral reef rehabilitation projects in an effort to restore the degraded reefs. These projects have been initiated in both the Gulf of Thailand and the Andaman Sea, and implemented with a range of objectives and using different methods (Yeemin et al. 2006). The most common method used in Thailand during the past 10 years has been coral transplantation. Like in many other areas of the world, the coral species used for this purpose were mainly branching corals, i.e. *Acropora* and *Pocillopora*. Branching species recruited well and grew fast (Yap et al. 1992; Bowden-Kerby 1997), but their high mortality rates (Clark and Edwards 1995), their susceptibility to bleaching when stressed, and their susceptibility to disease are significant risks associated with transplantation and reef restoration projects which rely on these species (Edwards and Gomez 2007). By contrast, massive species grow more slowly but they are more resistant to bleaching, and their solid, hard structure enables them to withstand storms and strong waves, thus they are likely to survive better. Few rehabilitation studies have focused on massive coral species due to their slow growth rate and greater difficulty to transplant. However, massive corals are major reef building blocks and many of them are more resilient to natural disturbances, thus more attention should be paid to their use in transplantation.

We chose to study *Porites lutea* transplantation as it is the major reef building species of the Andaman Sea and it has shown some resilience to major natural disturbances such as *Acanthaster planci* outbreaks, increases in sea surface temperature, and storms (Phongsuwan and Chansang 1993). At Maiton Island, unattached or loose *Porites* are common on the sea floor at a depth of 3-5 m. Unless they are attached to a substrate, these corals tend to have a poor chance of survival. In this study, survival and growth of different sizes of both fragments and unattached colonies following transplantation were investigated.

Materials and Methods

Study site

The study was carried out from November 2005 to June 2008 at Maiton Island, 8 km off the southeastern Phuket coastline (Fig. 1). The coral community on the island's northeastern side, where the study took place, lies on a flat sea floor at a depth of about 3-4 m below

mean sea level. In May 1986 the coral reef at Maiton Island and shallow water reefs nearby were severely damaged by a storm and coral recovery has been very low in comparison with reefs nearby (Phongsuwan 1991). The staghorn coral, *Acropora* spp., used to be the dominant genus as shown by debris in the area, but our survey in 2007 on the coral colonies settling on natural substrate found that corals at Maiton Island were dominated by *Porites* and *Millepora* which comprised of 90.48 and 2.69 % of total living corals in the area, respectively. The density of unattached massive coral colonies, including *Porites lutea*, was 1.72 colonies m^{-2}.

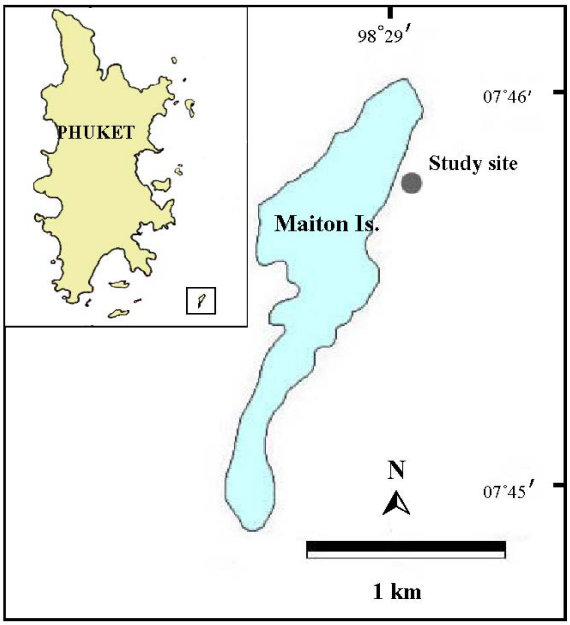

Figure 1: Study site at Maiton Island, Phuket

Transplantation and monitoring

1. Using a hammer and chisel, fragments of *P. lutea* were removed from intact donor colonies and divided into three different sizes, 5.0 x 5.0 cm (large fragment, FL), 3.5 x 3.5 cm (medium-size fragment, FM) and 2.5 x 2.5 cm (small fragment, FS). 45 replicate fragments of each size were generated.
2. Unattached *P. lutea* colonies, which were found on the adjacent seabed, were collected and sorted into 3 size classes as above (small colony, CS; medium-size colony, CM and large colony, CL). 30 replicates of each size were collected.
3. All fragments and unattached colonies were attached to 16 x 28 x 8 cm hollow blocks. Three corals were attached per block using quick drying cement. The blocks with the corals were placed at the same depth as corals were taken.
4. Measurement of the coral transplants was made by scuba divers. Using callipers, the maximum diameter and colony height of the living parts of all colonies were measured every 3-4 months. Survivorship, mortality and detachment of corals from the substrates were also monitored during each survey.

Data analysis

Survivorship, detachment and *in-situ* mortality were calculated as percentages of initial samples under monitoring. Overall survival was defined as the percentage of corals which had suffered neither detachment nor *in-situ* mortality. Growth was measured as both increase in colony area and colony height. Growth of transplanted *P. lutea* in this study predominantly involved horizontal expansion as shown in Fig. 2. Thus colony plan area was calculated by the formula πr^2 with assumption that colonies were circular in shape and r was equal to maximum diameter divided by 2. Regression analysis of growth pattern was done using Microsoft Office Excel 2003. Colony area increased exponentially and colony heights increased linearly. Thus for colony area, the horizontal growth constant (k) for each treatment was calculated using equation:

$$k = (LN(A_t)-LN(A_o))/t$$

where LN is the natural logarithm, A_o is the initial area measurement, A_t is the last area measurement available, and t is the time between measurements in years. Growth rates in terms of colony height increase were expressed as the slope of linear plots

The difference in growth, both in terms of transplant area and height, were compared using ANOVA (SPSS version 15.0). S-N-K tests were employed to determine which treatments differed.

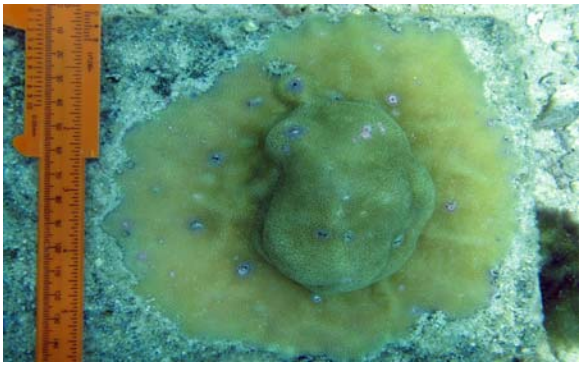

Figure 2: *Porites lutea* colony growing on a hollow cement block two years after transplantation.

Results

The percentage overall survivorship, in-situ mortality and detachment of fragments and colonies after transplantation are shown in Fig. 3. Almost three years after transplantation, the medium-size colonies and fragments, showed the highest survivorship, followed by large fragments, large colonies and small colonies. The small colonies and fragments had very

low survivorship (23.3% and 2.2%, respectively), comprised of a high detachment rate (63.3% and 66.7%, respectively) and in-situ mortality (13.3% and 31.1%, respectively). The high detachment and in-situ mortality occurred 150-300 days after transplantation during the Southwest monsoon season (June-October 2006). Subsequently, detachment and mortality rates of small transplants were similar to other treatments.

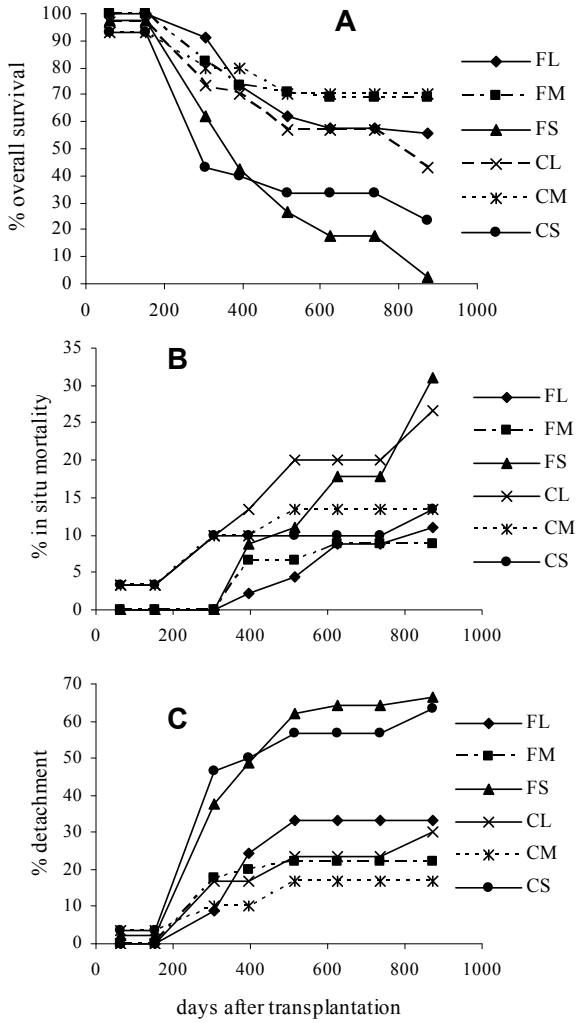

Figure 3: Percentage overall survival (A), *in situ* mortality (B) and detachment (C) of *P. lutea* fragments and colonies after transplantation.

Growth of the transplants

Most corals, both fragments and colonies of all sizes, started to self-attach by growing their basal plate over the cement blocks within two months of transplantation (Fig. 4).

Transplants showed a trend of exponentially increasing area with time (Fig. 5) and a trend of linear increase in height (Fig. 6). Growth rates expressed as increasing area and height per year are shown in Table 1. The growth constant (k) of coral fragments varied from 1.10 yr^{-1} for large fragments to 1.79 yr^{-1} for small fragments, while that of colonies varied from 0.91 yr^{-1} in large colonies to 1.68 yr^{-1} in small colonies. The growth constant of small colonies was significantly higher than that of large colonies (S-N-K, $p = 0.021$).

The colony height began to increase about 6 months after transplantation. Rates of increase in colony height of coral fragments were 0.58, 1.21 and 1.75 cm yr^{-1} in small, medium and large fragments respectively, and were significantly different (S-N-K, $p = 0.024$). Rates of height increase in colonies of different sizes did not differ significantly.

Table 1: Growth rates expressed as growth constant for increase in colony area and annual rate of increase in colony height of transplanted fragments and colonies

Category	Area growth constant, k (yr^{-1})	Height increase (cm yr^{-1})
FL	1.10	1.75
FM	1.39	1.21
FS	1.79	0.58
CL	0.91	2.12
CM	1.28	2.08
CS	1.68	2.15

Discussion

Our study found that it is possible to use fragments and unattached colonies of the massive coral, *P. lutea*, in the rehabilitation of degraded coral reefs. Instead of disturbing donor reefs by using whole large coral colonies, fragments were used. In addition attaching small loose colonies to hard substrata enhances their survivorship which assists natural recovery.

To minimize mortality and detachment of transplanted corals, an appropriate size must be used. Small fragments (2.5 x 2.5 cm) showed high detachment and did not survive well under this study. Although large fragments have a better chance of survival and grow faster than small fragments, breaking too large fragments may put stress on intact donor colonies and affect their growth. Medium-sized fragments grew at similar rates to the large fragments while their chances of survival were higher and their use puts less stress on donor corals than large fragments. Therefore, medium-size *P. lutea* fragments (3.5 x 3.5 cm) appeared most suitable for transplantation at Maiton Island or other areas where the environmental conditions are similar. Likewise, medium-size colonies showed good survival and similar growth rates to the large-size colonies, thus no significant benefit appeared to be gained by using 5 cm as opposed to 3.5 cm colonies.

In a previous study it took at least 7 years for transplanted *Porites lutea* fragments at Maiton Island to cover fully the cement blocks and blend with the natural surroundings. The mean growth of these coral colonies was 2 cm yr^{-1} in height (Thongtham et al. 2003) which is comparable to this study (0.6 to 2.2 cm yr^{-1} in height). Growth of the transplanted colonies at Maiton Island was comparable to growth of *P. lutea* (1.11 to 2.43 cm yr^{-1}) in natural coral reefs at Cape Panwa, Phuket Island (Charuchinda and Chansang 1985).

Analysis of reef fish abundance in the Gulf of California, and projection of changes by global warming

A. Ayala-Bocos, H. Reyes-Bonilla*

Universidad Autónoma de Baja California Sur, Departamento de Biología Marina, Laboratorio de Sistemas Arrecifales. La Paz, B.C.S., México. hreyes@uabcs.mx

Abstract. The Gulf of California has high endemism and diversity of its reef fish fauna. This study analyzes the abundance of 20 dominant species in the region, and evaluates possible changes to be caused by temperature increments. Stationary censuses of fishes were done in six regions during 2006, and oceanographic information for each one, including mean, minimum and maximum surface temperature, photosynthetic pigments, and nitrate, phosphate and silicate concentrations, was gathered. These factors were included in stepwise regressions to evaluate its influence on individual species, and the equations were used to project change in abundance as a result of warming in accordance to three scenarios: +1°, +2° and +3°C. The models indicated that as temperature rises, 4 species may reduce their abundance, 14 increase it and 2 may remain stable; also, 6 species may extend their geographic ranges. At community level, richness, taxonomic distinctness, diversity and average trophic level will likely increase with temperature, but the latter two will eventually return to their original levels. In conclusion, the Gulf of California fish fauna will not react homogeneously to the warming; some species may change their distribution and shifts in composition and structure are expected. These events may cause an ecological imbalance in teleost assemblages, and consequently affect the functions of the reef ecosystem in the gulf.

Key words: Temperature increase, distribution, community structure.

Introduction

The Gulf of California is recognized by its high endemism, diversity and biomass (Roberts et al. 2002, Mora and Robertson 2005), and consequently this inner sea represents one of the main areas for reef fisheries in México (SAGARPA, 2000). The Gulf is home to about 800 fish species, 271 of which are resident of rocky and coral reefs (Thomson et al. 2000), and they play a key role in these systems because their abundance and biomass makes them key elements in local trophic webs, and in the energy flow between neighboring biomes (Mumby et al. 2007).

Studies of the Intergovernmental Panel of Climate Change mention that in the last 30 years the atmospheric temperature increased between 0.3° and 0.6°C, and different models show that it will rise between 1.4° and 5.5°C by the end of the century (IPCC 2007). The panel also suggests that each of 1°C atmospheric increase, will lead to an 0.5° increase in the ocean. Many have indicated that reef faunas will be much affected by warming (Roessig et al. 2004; Perry et al. 2005; McKenzie et al. 2007). Fishes can be particularly disturbed by higher temperatures because they are ectotherms and mobile, and thus modifications in their occurrence and abundance can be rapidly detected (Bellwood et al. 2006).

The increasing trend of sea temperature worldwide is not homogeneous, as local and regional conditions have a definite influence (IPCC 2007; Hayes and Goreau 2008). However, it is important to generate scenarios in order to predict the potential impact of warming in local ecosystems, and from there provide recommendations to managers and government officials. Under this perspective it is especially relevant to analyze the current distribution, abundance and richness of marine resources exploited by man, and to plan ahead; this can support preservation of the assemblages and sustainable development. This paper presents an analysis of the current state of the abundance of 20 common fishes from the Gulf of California; we prepared numerical models for each species to predict changes in abundance and distribution under different levels of temperature increase. The results indicate that each species will behave differently and thus it is not expected that the fish assemblages in the Gulf of California will change in unison in the near future. Because of this idiosyncratic situation, it is possible that that global change will eventually have a strong effect on the function of the reef fish faunas, even when their composition may not change that much.

Material and Methods

The work was conducted in The Gulf of California, México. It is an inner sea adjacent to the Pacific Ocean, with a mixture of tropical and sub tropical waters and considerable differences in temperature between the north (average ~22°C, range 14° to 31°C) and south (average ~25°C, range 18° to 30°. Thomson et al. 2000). Stationary census (N=147) were done in six regions (Fig. 1); Los Angeles Bay (28°N), Santa Rosalía (27°N), Loreto (26°N), La Paz Bay (24°N), Cabo Pulmo (23°N) and Los Cabos (22°N). Fish abundance was estimated by counting fishes moving across observations cylinders of 5 m radius (79 m^2 sampling area), in a time period of 15 minutes. Of this interval, 5 minutes were dedicated to register species, and the following 10 to count individuals (Villarreal-Cavazos et al. 2000). The censuses were conducted in 2006, at a depth range between 5 m and 15 m, where reef fish abundance is higher (Alvarez-Filip et al. 2005; Robertson and Allen 2006). The studied regions present predominantly rocky bottoms with low coral cover (ranging from 20% at Cabo Pulmo, to 2% or less from Loreto to Los Angeles Bay; Reyes Bonilla and López Pérez, in press).

Each surveyed site was referred to a single 1° x 1° latitude-longitude cell, and for each of the six quadrats we obtained the mean, minimum and maximum surface sea temperature (°C), from the Reynolds SST analysis (1982 to 2006; www.nhc.noaa.gov/aboutsst.shtml), average photosynthetic pigments concentration (mg/m^3) from the SeaWifs and MODIS satellites (www.science.oregonstate.edu/ocean.productivity/custom.php; 1997 to 2007), and the mean nutrient concentration (nitrate, phosphate and silicate; μM), from the World Ocean Atlas 2005 (http://www.nodc.noaa.gov/OC5/SELECT/woaselect/woaselect.html), from 1950 to 2004.

Before conducting the numerical analysis, we selected the 20 most abundant species of the full database which included over 80 taxa seen in the six visited regions, These 20 species belong to six families and as they occupy different reef habitats and present a variety of morphologies, food sources and life histories, we considered them as good representatives of the entire fish community. To generate models for prediction of abundance of each fish species in accordance with environmental factors, we used stepwise regressions; this technique also allowed us to quantify the influence of each oceanographic indicator on abundance. All data were standardized, and to avoid autocorrelations the regressions were run with the "ridge" routine, using a tolerance of 0.00001 (Neter et al. 1996).

The next step was to evaluate the possible impact of ocean warming on the targeted fish species, using three possible scenarios considered by the IPCC: increment of 1, 2 and 3°C. To do so, we directly replaced the value of the new coefficient of temperature in the regression equations, when this attribute was a part of the model. In addition, the coefficients of the remainder oceanographic features were adjusted correspondingly with the proposed warming by using the estimated value obtained from linear regressions of temperature and each factor, in order to predict its response to elevation of 1° to 3°C. With these corrections the final models were more complete and able to predict the joint effect of several environmental factors at the same time. When temperature was not selected by the stepwise procedure, we only used the modified parameters in the models of fish abundance.

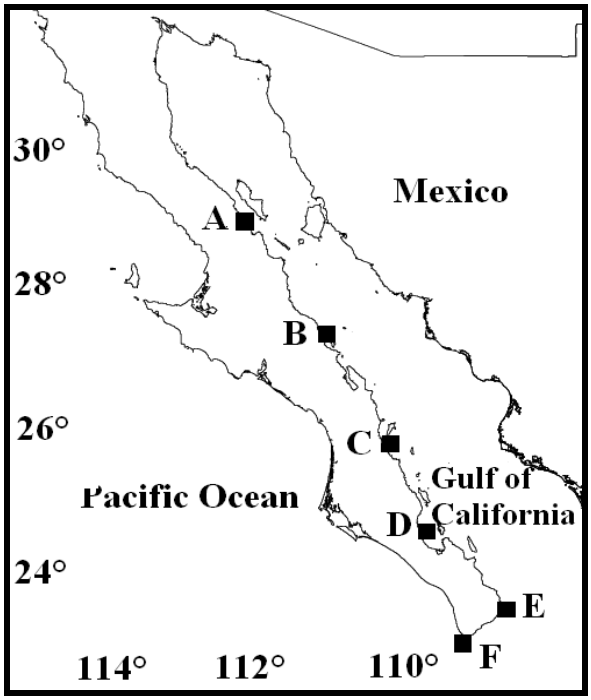

Figure 1: Study regions in the Gulf of California, Mexico; A) Los Angeles Bay, B) Santa Rosalía, C) Loreto, D) La Paz, E) Cabo Pulmo and F) Los Cabos.

Finally, we tested the consequences of changes in individual species at a higher hierarchical level by generating "future" communities from the predicted abundance of the 20 species. Then, for all regions and scenarios we calculated four ecological indices: richness, Shannon-Wiener diversity, taxonomic distinctness, and the similarity of the predicted communities to the actual data using the Bray-Curtis coefficient, and performed a cluster analysis, comparing all regions and scenarios.

Results

There were four different types of response in the 20 studied taxa. First, the models suggest that four species could reduce their abundance, including the now widespread damselfish *Abudefduf troschelli*. It is relevant to notice that the predictions point out to the eventual disappearance of a Gulf of California endemic *Chromis limbaughi*, the blue-yellow damselfish, in the northern gulf (Fig. 2).

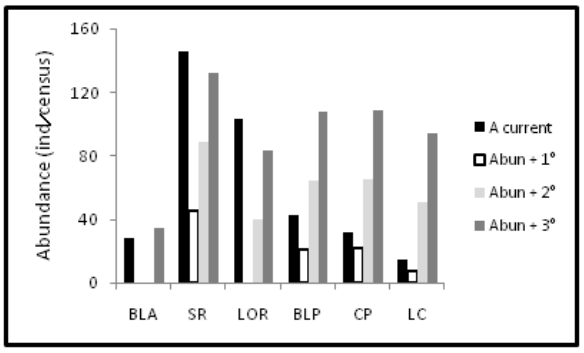

Figure 2. Current and predicted abundance of *Chromis limbaughi*.under three different scenarios of temperature increment

Other 13 species could increase their abundance and in some cases their numbers may become very similar in all areas of the Gulf (Table 1). One of them is very important for the aquarium trade (the Cortes angelfish *Holacanthus passer*), and among the rest there are two very common fishes: *Chromis atrilobata* (spot damselfish) and *Thalassoma lucasanum*, (the rainbow wrasse), as well as a key commercial species, the yellow snapper *Lutjanus argentiventris*. Finally, two species (a haemulid and a snapper) show no change caused directly or indirectly by the warming, possibly indicating a wide physiological tolerance.

Table 1 Predictions of change in abundance and geographical range of the 20 analyzed species, with temperature increases.

	Abundance		
Range	**Increase**	**Decrease**	**Same**
Increase	*P. punctatus* *C. puctactissima* *S. flavilatus* *C. oxycephalus* *S. ghobban* *T. grammaticum*		
Decrease		*A. troschelli* *G. simplicidens* *C. gracilis* *C. limbaughi*	
Same	*M. dentatus* *H. passer* *B. diplotaenia* *C. atrilobata* *T. lucasanum* *S. rectrifaenum* *L. argentiventris* *H. flaviguttatum*		*P. colonus* *H. maculicauda*

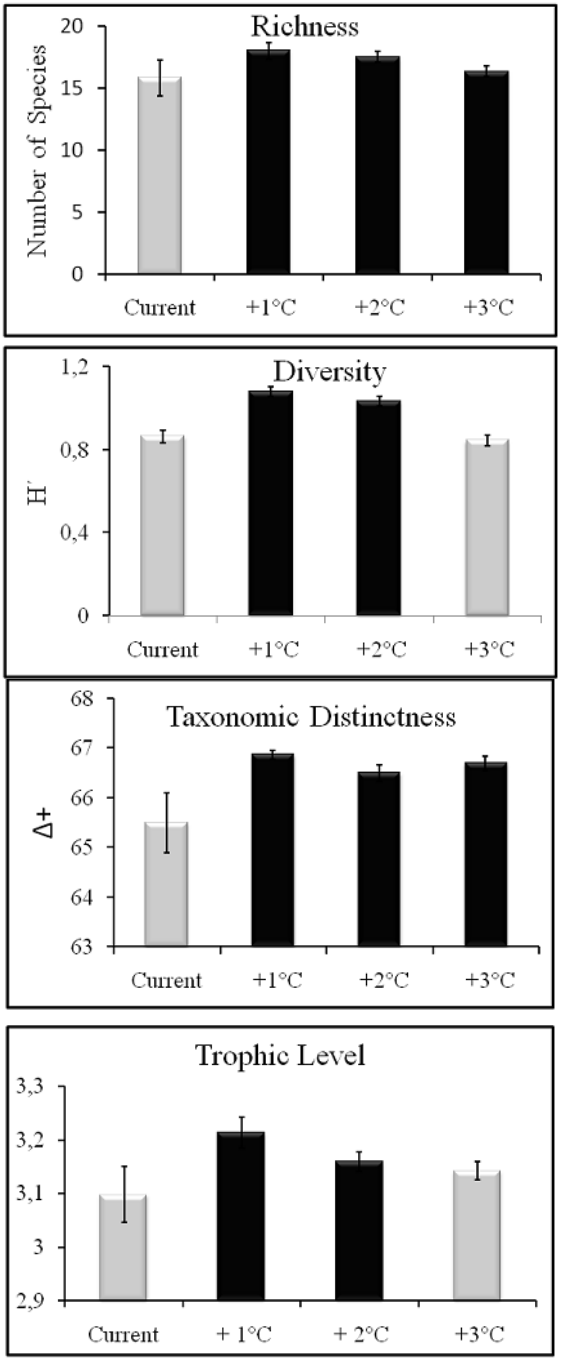

Figure 3. Changes in fish community structure according to three possible scenarios of global warming. Bars signal the average and SE, and those with the same color had no significant differences, according to Kruskal-Wallis tests.

Related to changes in distribution, six species could extend their ranges to areas where they are currently absent, in specific Los Angeles Bay. In this case we have a commercial species (*Scarus ghobban*) and a very important herbivore *(Prionurus punctatus*).

Another four species will likely have a more restricted range, and 10 apparently will be unaffected (Table 1).

The community analyses evidenced that richness, diversity, taxonomic distinctness and trophic level, significantly increase when the temperature rises 1°C. However, their values gradually lower, and in the case of diversity and trophic level at +3°C, they even return to approximately the same level they were before temperature changed (Fig. 3). Finally, the dendrogram (Fig. 4) shows that the fish communities will change depending on the temperature increase from their original condition (left side of the tree), to +3° (right side). Notwithstanding there will be a mix of assemblages since conditions starts to change, meaning that the compositional shift will not be completely ordered.

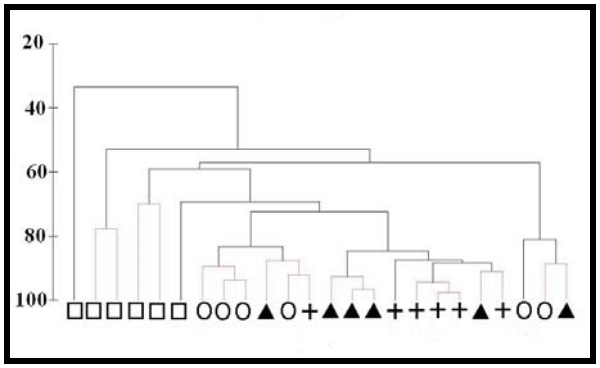

Figure 4. Dendogram showing the similarity in the current and the projected assemblages. Key: squares= actual assemblage, circles= +1°C, triangles= + 2°C; crosses= + 3°C.

Discussion

The model tested in this paper considers the response of 20 fish species to potential changes in a set of oceanographic variables including productivity and nutrient concentration; nevertheless, the forecasting is ultimately based on how sea surface temperature will increase in the Gulf of California. There are several reasons why this choice was made; first, global change models only consider sea temperature and salinity as there are excellent long-term data on the former factor, and the second can be predicted accurately from the first (IPCC, 2007). In addition (as it was done in this paper), the relation between temperature and other chemical forms in the ocean can be locally or regionally modeled (Kamykowski 2008; Silió-Calzada et al. 2008) but the link breaks at a global scale. Consequently, Donner et al. (2009) recommend that analyses of the response of reef faunas to global change should focus on temperature increase, and this justifies why most studies on the future of reef corals have also followed this approach (Sheppard 2003; Donner et al. 2005).

There are other variables which may affect the response of reef fishes to ocean warming (Baker et al. 2008; McClanahan et al. 2009). They include changes in habitat quality (specifically loss of coral cover and reef structure), in ocean circulation (which will affect dispersal and recruitment), and in acidity. Considering the first topic, reef coral cover is low along the Gulf of California (Reyes-Bonilla and López-Pérez, in press). As a consequence, most reef fish species of the Gulf of California do not depend on the presence of corals for their settlement, feeding or protection, as shown by their community stability even after severe bleaching and mortality events (Alvarez-Filip et al. 2006). For that reason we suggest that the ocean warming will not affect significantly the condition of the local fish habitats, and thus the factor was not examined here.

In relation to ocean acidity, there are worries that a lower pH can affect metabolism, larval development and other aspects of the life history of the ichtyofauna (Baker et al. 2008). Unfortunately the situation is still not clear, and Munday et al (2008) stated that any kind of prediction is still speculative as the experimental and field evidence is scant. Something similar can be said about ocean currents as there are contrasting views on the subject (IPCC 2007). Considering this, we decided not to include any of these factors in the regressions.

One of the key findings of this study is that the reef fishes of the Gulf of California will not react homogeneously to temperature increases. This was expected since the fish assemblages of the Gulf are formed by a mixture of tropical and temperate faunas (Thomson et al. 2000), with different niches and ecological requirements, and which will adjust differentially (or not at all) to oceanographic changes. Table 1 indicates that the most affected species (with reduced abundance and distribution range) are adapted to warm or cold water (*Abudefduf troschelli* and *Girella simplicidens*); probably the former will disappear because their upper temperature tolerance levels are reached, and the latter if the Gulf becomes too warm (Roessig et al. 2004; Perry et al. 2005). However, the models indicate that most species will benefits from the warming by either increasing their geographic range or their local population sizes (Table 1). A good explanation for this situation is that as practically all of the studied taxa are distributed in the Panamic Province, they are adapted to tropical conditions (Fiedler and Talley 2006) and then the ocean warming will provide them a more adequate habitat in the Gulf of California.

It was interesting that the ecological indices reach higher values with temperature increases (Fig. 3). This possibly results from the concurrent rise in richness and abundance of the fishes (especially in the

northern Gulf), but the change is not "permanent" as diversity and average trophic level return to the values of 2006. This finding points out that the effects of global change may be subtler than imagined, and that as proposed by Bellwood et al. (2006), traditional ecological indices may not be good indicators of effects on ecosystem condition. However, note that taxonomic distinctness remained high, indicating a more homogeneous distribution of abundance and species richness in higher taxonomic groups in the future. This metric is recognized as a good indicator of biodiversity (Magurran 2004), and its response in this paper indicated that it can be a good choice to depict future changes in the fish faunas.

According to the dendrogram (Fig. 4), the compositional changes caused by higher temperature may be relatively orderly, but nevertheless the shift in ecological function of the resident species (shown by the average trophic level; Fig. 3), point out to possible ecological imbalances in reef fish assemblages of the Gulf in following decades; these in turn may translate to potential economic impacts. A similar statement has been done in relation to previous modifications in fish abundances along the Gulf, in particular the depletion of larger carnivores (Sala et al. 2004). The combination of unsustainable fisheries and global change may bring a bleak future for reefs in this region.

In conclusion, our results show that fish species of the Gulf of California might respond differently to increases in ocean temperature and thus the communities will not change as a unit. Because of these qualitative changes, global warming might have severe effects on the function and productivity of the local reef ecosystem.

Acknowledgements

We thank Francisco Fernández (COBI, A.C.) for arranging and preparing the fish abundance data base. The paper was discussed by the rest of members in the Reef Sytems Laboratory, and for the analysis and collection of oceanographic data we received help from Salvador Lluch (CIBNOR, La Paz). One anonymous referee provided comments and suggestions that improved the paper.

Abstract: Coral reef fishes will be increasingly exposed to habitat degradation as climate change increases the frequency and intensity of coral bleaching events. This study explores how body colouration influences survivorship of coral-dwelling fishes during coral bleaching events. Specifically, we tested for differences in the vulnerability to predation between a bright yellow fish (*Pomacentrus moluccensis*) and a white/black fish (*Dascyllus aruanus*) in a range of different coral habitats, including healthy, bleached, recently dead and algal-covered coral colonies. Strike rates by predators against both damselfish species increased in bleached and dead coral habitats, compared to healthy coral habitats. There was no differences in strike rate towards either species of fish in any of the habitat conditions tested, suggesting that both the yellow and black/white colouration is equally visible to the predator (*Pseudochromis fuscus*). However, survivorship on bleached corals was lower for *D. aruanus* than for *P. moluccensis* suggesting that coral bleaching may have a disproportionate effect on brightly coloured reef fishes.

Key words: Climate change, Coral bleaching, Reef fishes, Habitat degradation, Selective predation

Introduction

Corals are essential for the survival of many species of coral reef fishes as they are the primary habitat-forming species in coral-reef environments (Connell et al. 1997). Live coral is a source of shelter, food and recruitment for many coral reef fishes (Pratchett et al. 2008, Jones et al. 2004) while increased topographic complexity moderates competition and predation (Beukers and Jones 1997, Holbrook and Schmitt 2002, Almany 2004). Coral cover and diversity can positively influence the abundance and diversity of coral reef fishes (Bell and Galzin 1984, Carpenter et al. 1981, Munday et al. 1997, Ohman and Rahajasura 1998) and changes in the condition or abundance of coral reef habitat may have considerable consequences for biotic interactions, abundance and diversity of reef fish assemblages (Syms and Jones 2000, Munday 2004, Pratchett et al. 2004, Wilson et al. 2006).

The pervasive view in literature investigating effects of climate-induced bleaching on fishes is that populations decline as a result of a loss in habitat structural complexity following bleaching induced coral loss (Lewis 1997, Bergman et al. 2000), while coral mortality *per se* has limited effects on fishes (Sale 1991, Lindahal et al. 2001). However, several recent studies suggest that mere bleaching of corals can have a detrimental effect on coral reef fishes, especially among those species that inhabit live corals (Ohman et al. 1999, Jones et al. 2004). Decline in the abundance of coral-dwelling fishes following host coral bleaching may be attributable to either movement of fishes to alternative habitat colonies, or mortality, which probably results from increased susceptibility to predation (Wilson et al. 2006, Pratchett et al. 2008). Coral-dwelling fishes may face an immediate increase in susceptibility to predation due to the increased conspicuousness of prey fishes against the white background of bleached corals.

Increased levels of predation could possibly be influenced by a reduction in camouflage of brightly coloured reef fish against the now pale/white habitat background. Different coloured fish associated with habitats exhibiting different levels of pigmentation are therefore predicted to experience a difference in their visibility to predators. Most coral-dwelling fishes are vividly coloured with yellow, blue, green and red which are important in communication and signalling (Lorenz 1962) and can be an effective camouflage against coral habitats (Cott 1940, Marshall 2000). It seems intuitive that brightly coloured fishes should be much more apparent against a bleached-white background, compared to the pink or brown hues of live coral. This contrast between coral-dwelling fishes and pale/white bleached coral is predicted to increase the risk of predation for

brightly coloured fishes as they contrast against the degraded background.

The aim of this study was to compare predation risk of two coral-dwelling damselfish with highly contrasting colouration; one that is bright yellow: *P. moluccensis*, and one that is black and white: *D. aruanus*. The two contrasting fishes were presented to predators against different habitat backgrounds to test if there was a change in the visual detection of prey by a common predator when associated with healthy, bleached, dead and algal-covered coral habitats. Survivorship was also measured across the four different habitats to test the efficiency of the predators at capturing the two different coloured prey. Marshall (2000) found that the yellow coloration in fishes were a very close match to average reef colour with a colour distance of 0.04. Fishes also lack long wavelength photo receptors (Marshall 2000) meaning that yellow will be well camouflaged against an unbleached reef backdrop but will render them more obvious to predators against bleached white coral. The bright yellow colouration of *P. moluccensis* was expected to be more obvious to the predator against the bleached and dead background than the white/black colouration of *D. aruanus* and therefore *P. moluccensis* was expected to elicit a higher number of strikes and have lower survivorship in bleached habitat.

Materials and Methods

This study was conducted in April 2007, at Lizard Island Research Station (14°40'S, 145°28'E), on the northern Great Barrier Reef (GBR), Australia. Aquaria-based experiments were used to test the apparent conspicuousness of prey fish and compare predation risk in different habitat conditions. Coral habitat used in the experiments was *Pocillopora damicornis*, a common branching coral that is highly susceptible to bleaching (Marshall and Baird 2000) and used by many coral-dwelling fishes for habitat (Pratchett et al. 2004). Healthy and algal-covered colonies of similar size and complexity were collected from the lagoonal area. One third of the healthy colonies were randomly selected and subjected to osmotic stress (100% freshwater for 5 mins) to induce bleaching (Kerswell and Jones 2003). This was signified by a reduction of pigmentation within the live coral tissue. Another third were placed into a chlorine solution and rinsed well to remove all living tissue leaving bare white skeleton. Healthy and algal-covered colonies were kept in high flow-through tanks to ensure that they did not degrade.

Juvenile *Pomacentrus moluccensis* and *Dascyllus aruanus* (12-32mm in total length) were used in experiments. Both these planktivores associate with live branching coral and take refuge within the branches of their host coral colony when threatened (Allen 1991). *Pseudochromis fuscus* (53-72mm in total length), was selected as the predator to use in experiments because it a common resident predator on small coral-reef fishes and amenable to experimentation and to aquarium conditions (McCormick and Holmes 2006). Both prey fish and predators were collected from reefs within the Lizard Island lagoon using the anesthetic clove oil and small hand nets. Prey fish were kept in groups of up to ten individuals and fed daily using manufactured aquarium food. Predators were kept in separate aquaria due to their aggressive nature and starved a minimum of 2 days prior to each experiment. Each fish was used only once per trial for each experiment.

To test if the visual detection of two different coloured fish by a common predator varied against different backgrounds, individual juvenile *P. moluccensis* and *D. aruanus* were placed before life-sized laminated photos of i) healthy, ii) bleached, iii) dead and iv) algal-covered colonies. The use of photographic images was used to help eliminate variation in habitat complexity and olfactory stimuli that might influence predatory behaviour. The four pictures were fixed equal distance from each other around the periphery of a large circular plastic tub (113cm dia.). The bottom of the tub was covered in a thin layer of sand and the water level adjusted to the top of the pictures so that the predator remained at eye level to the image. An individual prey fish was placed within a small clear zip-lock bag (50 x 100mm), flooded and placed in front of an image. A predator was released onto a small fragment of coral in the centre of the aquarium. Each trial ran for 20 minutes and the number of strikes against prey in front of each habitat image during this time was recorded. Only one species of prey was used for each trial and each individual prey and predator was replaced after the completion of a trial.

If live, healthy coral provides effective camouflage for brightly coloured reef fishes, such as *P. moluccensis*, we predicted that strike rates by predators would be lower for prey placed in front of images of healthy colonies compared to bleached or dead coral colonies. We also predicted that strike rates would be higher for the bright yellow coloured *P. moluccensis* compared with *D. aruanus*. The black and white colouration of *D. aruanus* might be expected to offer better camouflage against bleached corals than the bright yellow colouration of *P. moluccensis*. Variation in strike rates between the two coral-dwelling fish

was tested in a MANOVA, as recommended by Roa (1992) because individual strikes by predators might not be independent of each other.

Secondly, tests of survivorship with varying habitat condition were conducted to test predation rates. Here prey fishes were subject to predation by predators by placing four prey fish and one predator within an aquarium with one of the four different habitat treatments. Two individual *P. moluccensis* and two individual *D. aruanus* were placed within a glass aquarium (60 x 30 x 40cm) and survivorship recorded over a 75 hour period with the presence of a single *P. fuscus*. Each habitat treatment was replicated six times and survivorship compared. Two tanks were also run with the absence of a predator to control for tank and habitat effects on survivorship. Predators were placed into the tank at 17:00, one hour after the prey fish to allow them to acclimate to the tank and surrounding habitat. Variation in prey survivorship over 75 hours was tested in a MANOVA.

Results

The number of strikes against yellow versus white/black fish did not differ across the four different habitat conditions (MANOVA $F_{4,23}$=0.95, P=0.45). The number of strikes against both fish colours increased when the fish were presented against a background of bleached coral but decreased against backgrounds that depicted algal-covered coral (Fig.1). This suggests that there is no difference between the levels of visual perception between the two fish, even when placed before different habitat conditions. However, overall there was an increase in the number of strikes from healthy to bleached and to dead coral habitat, showing an increase in strike rates with coral degradation.

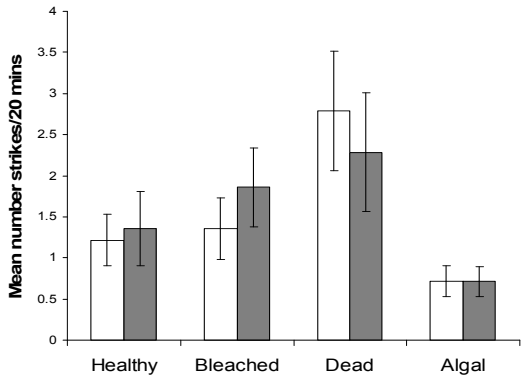

Figure 1. Mean number of strikes (±SE) against *D. aruanus* (□) and *P. moluccensis* (■) associated with four different habitat conditions over a 20 minute period.

In actual predation trials, survivorship between yellow and white/black fish was only significantly different for fish associated with bleached habitat (MANOVA F=7.10, df=1, P=0.04). In bleached coral habitats survivorship was twice as high for the white/black coral-dwelling fish (*D. aruanus*) compared to the yellow species (*P. moluccensis*) (Fig. 2). This suggests that the colour of prey fishes against their coral habitat is critical to evading predators and maximising survivorship.

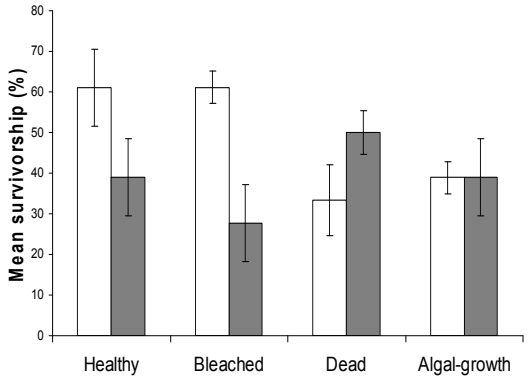

Figure 2. Mean survivorship (±SE) of *D. aruanus* (□) and *P. moluccensis* (■) associated with four different habitat conditions after being exposed to a predator for 75 hours.

Discussion

Predation is a fundamental process on coral reefs influencing the structure of ecological communities (Caley and St John 1996, Hixon and Carr 1997, Almany 2003). The effect that predators have on fish populations is largely driven by the method in which they select prey species and individuals (Hixon 1986). Furthermore, habitat complexity and habitat quality can certainly moderate the outcome of predator-prey interactions (Main 1987). This study explored if two different coloured fish vary in susceptibility to predation across a range of habitat conditions given that one species (*P. moluccensis*) is bright yellow and the other (*D. aruanus*) is white and black. We found that there was no significant difference in strike rates on these two contrasting prey fishes against a range of different background habitats and importantly, an increase with coral degradation for both fish colourations. Similarly, the survivorship of the two different coloured prey fish was broadly similar over a range of habitat conditions, except when the coral was bleached. In bleached coral habitats, it was clear that *D. aruanus* had a decided advantage in survivorship over *P. moluccensis*, possibly because bleached coral habitat continues to provide an appropriate background to minimise conspicuousness of white and black fishes.

Different predation rates on reef fishes associated with healthy, bleached, dead or algal-covered coral habitats is possibly a result of increased visual perception by predators. Many reef fishes are specifically coloured to camouflage against their habitat for hunting, hiding and signalling (Cott 1940, Marshall 2000). Camouflage is an important determinant in the distribution and habitat associations of many animals by matching body colouration with their surrounding habitats (Helfman et al. 1997). The similar strike rates on the two species of fish suggest that there was no difference in the visual detection by a predator of the yellow versus the white/black body colouration. Although the white/black colouration of *D. aruanus* might be expected to visually stand out against healthy and algal-covered coral habitats, there was no significant difference in the number of strikes observed compared with *P. moluccensis*. Both damselfishes received more strikes as the habitat degraded from healthy to bleached to dead colonies, although fish associated with algal-covered coral had the lowest number of strikes. Declines in the abundance of *P. moluccensis* immediately following coral bleaching have been repeatedly documented along with the declines in other coral-dwelling fishes (Booth and Beretta 2002, Pratchett et al. 2008). This is consistent with the expected visual contrast between fish and habitat. The low number of strikes for both prey colours on algal-covered coral might suggest that this dark brown/green habitat offers the best backdrop for the fish to camouflage against or that predators are used to looking for prey in healthy and similar looking habitats.

Survivorship between the two prey colourations was similar across the different habitat conditions except for bleached corals where mortality was slightly lower or *D. aruanus*. *Dascyllus aruanus* was expected to have better camouflage against the bleached habitat as the white background would have a reflectance similar to that of the fish; white fishes reflectance peaks between 330 and 390 nm while the black part has very low reflectance (Marshall 2000). This contrast between white and black could potentially provide disruptive camouflage that could confuse the predator against the bleached white background. Therefore, contrasting colour patterns as seen in *D. aruanus* could be just as important for predator avoidance as colour. The white and black contrasts could break up the body outline and confuse predators.

In conclusion, this study shows that bleaching is likely to have a disproportionate effect on brightly coloured fishes provided predation is the main proximal cause of mortality, and that colour vision plays a role in prey detection and predator avoidance through camouflage. While the predatory species used in this study (*P. fuscus*) is a conspicuous predator within coral habitats occupied by coral-dwelling damselfishes (Munday et al. 2003), it should be noted that other predators on coral-dwelling fishes may detect prey fishes at different distances or using other cues which may not be influenced by visual changes to habitat condition. Further research is needed to investigate how changes in habitat condition, through loss of pigmentation, live tissue cover and natural habitat structure, will impact the ability of coral-dwelling fishes to avoid predators. Colour could be one method of camouflage. Contrasting colour patterns may also be effective in reducing predation risk, especially in bleached coral habitat.

2) IUCN Global Marine Programme, P.O. Box 13513, Dar es Salaam, Tanzania

Abstract. The effect of elevated sea surface temperature (SST) on the coral reefs of the Gulf of Mannar, Southeastern India was monitored during 2005-2008 using quadrate and LIT methods. The pattern of effect was almost similar on the reefs every year except the modest fluctuations in the temperature levels. The temperature varied between 31.0^{0}C and 33.5^{0}C during summer (April - June). The major reef areas in the Gulf of Mannar are shallow, between 0.5-3.0 m depth and in general, comparatively high temperature prevailed and the reefs seem to be acclimatized to such situation. The average percentage of bleached corals during 2005, 2006, 2007 and 2008 was 14.6, 15.6, 12.9 and 10.5 respectively. The bleaching of corals was noticed from mid April and high temperature existed for about a month from the end of April. Massive corals especially *Porites* sp. were the first to be affected and the other dominant coral species partially / fully bleached were *Acropora cytherea, A. formosa*, *A. intermedia, A. nobilis, Montipora foliosa*, *M. digitata* and *Pocillopora damicornis*. The incidence of bleaching was not uniform every year, in terms of area and depth, but the pattern was same. Dependent on rainfall and winds, recovery began during June-July and completed in 1-4 months. The branching corals recovered quickly after temperature reduction, but massive corals took longer time. The fastest recovered coral size groups were 40-80 cm and 80-160 cm. There was no coral mortality in 3 years due to elevated SST, but 80% of the bleached recruits dead in 2007.

Key words: Coral reef, climate change, annual bleaching, SST

Introduction

Coral reefs appear to be undergoing worldwide decline (Epstein et al. 2001; 2003). An estimated 20% of coral reefs worldwide have been destroyed, while 24% are in imminent danger and a further 26% are under longer term danger of collapse (Wilkinson 2004). Although much of the coral reefs degradation is directly blamed on human impact, there are natural disturbances causing significant damage to coral reefs.Global warming is undoubtedly important, many instances of bleaching being correlated with increased temperature (Glynn 1991; Glynn 1993; Warner et al. 1999). Increased sea surface temperatures, decreased sea level and increased salinity from altered rainfall can all result from weather patterns such as El Nino (Forrester 1997). Unprecedented anthropogenic pressures on reefs have been exacerbated in the 1980s and 1990s by several strong El Nino Southern Oscillation events, which have been correlated with widespread warm water anomalies and associated bleaching and mortality of corals (Glynn 1984; 1993; Wilkinson et al. 1999).

Reefs in the Gulf of Mannar are developed around the 21 uninhabited islands that lie along the 140 km stretch between Tuticorin and Rameswaram of Tamilnadu, Southeast coast of India (Fig.1).

Figure 1 Map showing Gulf of Mannar

These islands are located between latitude 8º47' N and 9º15'N and longitude 78º12'E and 79º14'E and the average distance of these islands from mainland is about 8 km. The once rich reefs of Gulf of Mannar have been heavily exploited in the past 2-3 decades. Now, due to conservation initiatives, tightening of the enforcement and permanent halt of the coral mining, coral cover is increasing remarkably. However, significant coral bleaching was observed in the Gulf of Mannar in 2005. The present monitoring was initiated to collect baseline information on temperature variation and its impact on corals.

Materials and methods

The temperature was measured monthly in the reef areas of all the islands of the Gulf of Mannar during the period between 2005 and 2008 by digital thermometer. Permanent sites at each islands assessed the bleaching. Percentages bleaching during the summer months and recovery after consequent months were estimated using Line Intercept Transect method (English et al., 1997) and quadrate method.

Results

Temperatures in the Gulf of Mannar are never below 26 ºC. Summer temperatures (April to June) varied between 31.0º C to 33.5ºC. Sea surface temperature peaks during May (overall range 26.5 to 30.5ºC; Fig.2-3).

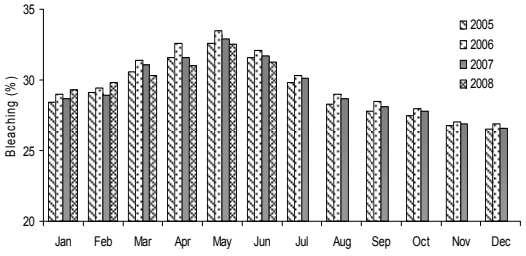

Figure.2: Average monthly SST values in the Gulf of Mannar during 2005 to 2008

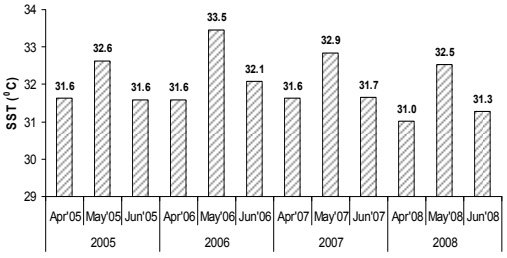

Figure 3: Sea surface temperature (^{0} C) in summer (April, May and June) during 2005 to 2008 in the Gulf of Mannar

Corals bleached every year since 2005 during summer starting from April. Average percentage of bleached corals was 15.6% during 2006, 14.6% in 2005, 12.9% in 2007 and 10.5% in 2008 (Fig.4).

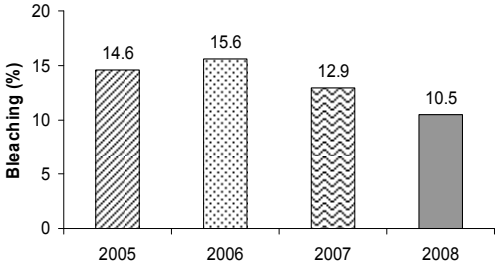

Figure 4: Percent of bleaching in summer (April, May and June) during 2005 to 2008 in the Gulf of Mannar

Massive corals especially *Porites* sp. were the first to be affected and the other dominant coral species partially or fully bleached were *Acropora cytherea*, *A. formosa, A. intermedia, A. nobilis, M. foliosa, M. digitata* and *Pocillopora damicornis*. *A. cytherea* bleached the most (2.91% during 2006) followed by *A. formosa* with 2.55%. In 2005 the most affected species was *A. cytherea* with 2.44% followed by *M. digitata* with 2.12%. In 2007, the highest affected was *Porites* sp. with 2.05% followed by *A. cytherea* and *A. intermedia* and in 2008 it was *Porites* sp. with 1.75% followed by *A. formosa* with 1.66%. The details are given in the Fig.5.

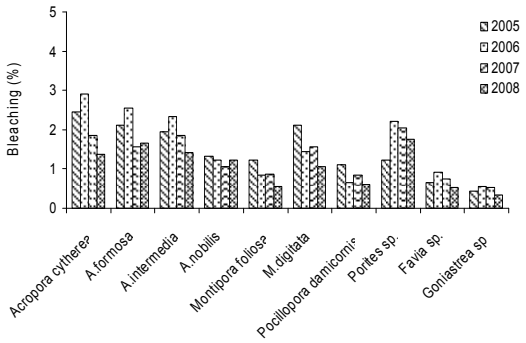

Figure 5: Percent of bleaching in common coral species in the Gulf of Mannar

Incidence of bleaching was not uniform every year in terms of area and depth, but the pattern was comparable. Depending on rainfall and winds, recovery began during June-July and was completed in 1-4 months. The branched corals recovered quickly after temperature reduction, but massive corals recovered slower.

The fastest recovered coral size groups were 40-80 cm and 80-160 cm. There was no coral

mortality in 4 years due to elevated SST, but 80% of the bleached recruits dead in 2007.

Discussion

The projected increases in ocean temperatures are expected to exacerbate the stressors already affecting many coral reefs, resulting in additional coral bleaching and mortality (Pockley 2000; Hughes et al, 2003; Pandolfi et al. 2003). However, the reported annual bleaching in the Gulf of Mannar did not result in any appreciable mortality, maybe because the area has already been severely disturbed. In the Gulf of Mannar, corals tend to bleach when exposed to 2 to 3ºC elevated temperature level in late April every year. Hoegh-Guldberg (1999) predicted that mass bleaching could become an annual occurrence by 2020 in Southeast Asia and the Caribbean, by 2030 on the Great Barrier Reef and by 2040 in the central Pacific. This prediction is already reality in the Gulf of Mannar since the bleaching event happens every year in the same time since 2005.

Corals that are regularly exposed to stressful environmental conditions have, in some cases, been shown to acclimatize and exhibit physiological tolerance to elevated temperatures and UV-radiation that exceed normal thresholds. Reef areas in the Gulf of Mannar are shallow, (0.5-3 m depths), and high temperature around 29ºC prevails throughout the year. Corals seem to be acclimatized but temperature over 31.0ºC causes bleaching and the corals start to recover when the temperature level falls to normal.

Factors influencing resistance of corals to high temperatures include extrinsic (environmental) factors such as strong water currents that reduce the severity of thermal stress (West and Salm 2003; Jokiel 2004), and intrinsic (physiological) factors such as incorporation of heat-resistant zooxanthellae clades (Baker 2004) and the production of heat shock proteins (Brown et al. 2002). Identifying and protecting habitats and colonies that are relatively resistant to high temperatures is important for conserving coral reefs in the face of global warming (West and Sal, 2003). In 2008, the percentage of bleaching was relatively low (10.5%) because of cyclone Nargis and subsequent rainfall and winds which reduced the temperature level by the end of May. There was no coral mortality in 4 years due to elevated SST, but 80% of the bleached recruits died in 2007. Despite this mortality, reefs in the Gulf of Mannar appear surprisingly resilient.

Abstract. The prevalence of bleaching was recorded in staghorn thickets of two back reef pools on a biweekly basis during the October to June bleaching season, and monthly basis for the rest of the year at Tutuila, American Samoa. Recording began in late 2003 and has continued since, and used a rapid visual estimation procedure. Three species of staghorns (*Acropora spp.*) in both pools bleached every Austral summer for five years. Reports of reef slope bleaching events in 2002 and 2003 imply that they bleached in those years as well. Thus, these corals have bleached for at least five summers and likely seven summers or more in a row. Other, less common species of *Acropora* and *Millepora* were observed to bleach as well. The bleaching displayed patterns consistent with the view that both temperature and irradiance are involved in producing the bleaching. The term "photothermal bleaching" was applied to this type of bleaching. This appears to be the first annual multi-species summer bleaching event reported.

Key Words: bleaching, annual, coral, staghorn, American Samoa

Introduction

Mass coral bleaching events have been reported on many coral reefs around the world (Brown and Ogden 1993; Glynn 1996; Brown 1997, Hoegh-Guldber, 1999, 2000; Wilkinson and Souter 2008). Although most corals recover in some events, in other events, many corals die. The intensity of the 1997-98 mass bleaching event was such that about 16% of the world's corals were estimated to have died in that event alone (Wilkinson et al. 1999). Much evidence links mass bleaching events with increased temperatures, and bleaching is predicted well by sea surface temperatures (SST; Hoegh-Guldberg 1999; McWilliams et al. 2005; Liu et al. 2003). The frequency and severity of events has been increasing (Glynn 1993; Hoegh-Guldberg 1999; Bellwood et al. 2004; McWilliams et al. 2005; Marshall and Schuttenberg, 2006). Global warming has been implicated in the increasing frequency and severity of mass bleaching and mortality events, and events have been predicted to continue to increase in frequency and severity, becoming annual summer events sometime in the future (Williams and Bunkley-Williams 1990; Ware 1997) with most predicting that to occur by about 2020 to 2050 (Hoegh-Guldberg 1999; Done et al. 2003). More severe events such as that in 1998 could devastate reefs by that time even though they would not occur every year, because reefs would require several years to recover from each event (Sheppard 2003).

Coral bleaching events on reef slopes was reported in American Samoa in 1994 (Goreau and Hayes, 1994), 2002 and 2003 (Green 2002; Craig et al. 2005), and caused some coral mortality on reef slopes. SST's for American Samoa show an increasing trend over the last 25 years (US EPA 2007). The observation of bleached staghorn corals in back reef pools of Tutuila, American Samoa in late 2003 prompted the senior author to begin monitoring bleaching in those back reef pools (Craig et al. 2005; Whaylen and Fenner 2006; Fenner et al. 2008; Fenner and Carroll in prep). *Acropora* and *Millepora* are reported to be among the most sensitive genera to bleaching (Marshall and Baird 2000; Loya et al. 2001)

Materials and Methods

Tutuila, American Samoa has nearly continuous fringing reefs on the south shore, with shallow reef flats and steep reef slopes (Craig 2005; Craig et al. 2005; Birkeland et al. 2008; Brainard et al. 2008; Fenner et al, 2008). At a few locations, sections of the reef flat have been dredged to provide fill for the airport runway or village land. These pools reach about 7-10 m depth at their maximum. These back reef pools are now co-dominated by *Porites*

cylindrica and the staghorn *Acropora muricata* (=*formosa*), with smaller amounts of the staghorns *A. pulchra* and *A. nobilis* (referred to as *A. intersepta* in some works). A few other species are scattered in these pools, including at least one stand of *Millepora dichotoma*, and individuals of a few other species of *Acropora*.

Staghorn thickets provide a particularly challenging subject for recording bleaching. Usually, the limits of colonies and clones are not clear. Further, bleaching commonly varies in intensity along the length of branches. In addition, what appear to be clones, and thickets, and different areas of the pools often bleach to different degrees. In most field studies of bleaching, bleaching is recorded by visual estimation. In this study, a rapid visual estimation method was used, in part because limited time was available for this study. A one hour swim over a fixed course was used, passing over two areas with different bleaching rates (Fig. 1), in each of two pools. A running estimate of bleaching was made during the swim, separately for each of the two different areas. At the airport pool, the area nearer to the runway typically was less bleached than the area farther from the runway. In the Alofau pool, the deeper eastern part of the pool always was more intensely bleached than the shallower western part. An area of staghorn was deemed bleached if at least part of branches were light or white on their upper surface only. The intensity of bleaching was not recorded. Bleaching was monitored biweekly when colonies were bleached, and approximately monthly when they were not bleached. Bleaching was also recorded on the reef flat and reef slope at Alofau beginning in January, 2007.

The satellite sea surface temperature (SST) is produced operationally by NOAA Coral Reef Watch in near real-time (http://coralreefwatch.noaa.gov). The SST values are produced globally twice each week and are ~9-km sub-sample averages presented on a 0.5-degree (approximately 50-km) grid (for detail see Skirving et al, 2006). The data used are from the pixel nearest the Airport Lagoon, just to the south, centered at [170.5W, 15.0S]. The warmest month climatology value used by Coral Reef Watch is representative of the expected summertime maximum temperature (and therefore a threshold for bleaching conditions) at this location. While not precisely co-located with the observation site, periods when the SST value exceeds the climatology at the offshore location are representative of when thermal stress is experienced near the coast.

Results

Porites cylindrica was not observed to bleach except at one small area in early 2007 (a patch on the reef flat in Faga'alu Bay). All three of the staghorn species were observed to bleach during the Austral summer at the Airport, Alofau, Nu'uuli, and Faga'itua pools. The Faga'itua pool is a maximum of 2 m deep and may be natural, while the other pools were produced by dredging. Bleaching typically involved lightening of color on the upper surface of horizontal branches, and when intense the entire upper surface was white. Lower surfaces always retained some color, except when a colony died. Polyps on the upper surfaces of a few branches died, while surviving on all of the rest of their surfaces and retaining color on their undersurface. Even during the Austral winter when very few staghorns were bleached, overturned colonies were observed bleached on what was previously their undersurface. Most years there was little if any colony death, but in 2007 in particular, some colonies died all except for branch tips, and a couple of thickets died completely. Thus, this is not just annual summer lightening of color (Fitt et al. 2000). Two of the staghorn species (*A. muricata* and *A. pulchra*) were found only in the back reef pools, but one (*A. nobilis*) was found also on reef slopes. *A. nobilis* was never observed to bleach on reef slopes at the same time it was intensely bleached in the back reef pools. On the reef slope at Alofau, *A. nobilis* on the reef slope at the same depth (about 4-5 m) as in the back reef pool of Alofau, was not bleached in 2007 when the colonies in the pool bleached sufficiently severely that only a few branch tips survived. *M. dichotoma* and some of the *Acropora* species other than the three staghorns were observed to bleach at the same time as the staghorns. A second, much less common bleaching pattern was for several centimeters of branch tips to bleach completely on all surfaces.

Water in the pools was typically warmer than the ocean, and at times could be felt to be warmer near the surface than deeper (the stratification likely due to low-wind conditions). Logger temperature records were obtained from 0.5 and 6 m at the airport pool, which reached maximum temperatures of about 32 °C for short periods midday. In Fagaitua, the logger at 2 m depth recorded a maximum of 34.9 °C for one half hour. That is a temperature similar to the maximum recorded in the back reef pools at Ofu Island in American Samoa, where a high diversity of corals lives (Craig et al. 2001). Staghorns there were moderately bleached at that time.

Staghorns in the Alofau pool bleached every summer (Fig. 1). Data for the deeper eastern area and shallower western area are plotted separately. As can be seen, the deeper area bleached more intensely and for a longer period than the shallow area. Bleaching began each year in October, and ended around the end of May or early June. For the deep pool, the onset

and end of bleaching was rapid, and bleaching was near 100% for most of the Austral summer. Staghorns in the deep pool spent most of the year bleached with only a short respite between years; despite this, corals manage to survive. Bleaching was much less intense on the reef flat, and near zero on the slope.

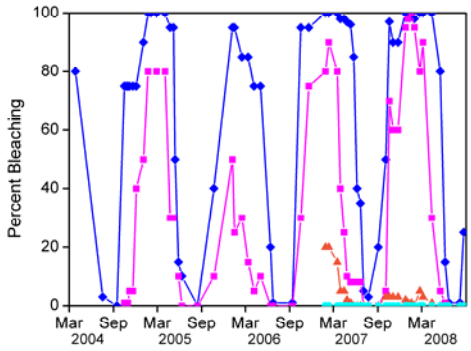

Figure 1 Staghorn bleaching observed at four sites at Alofau – left pool (blue diamond), right shallow (pink square), reef flat (orange triangle), reef slope (cyan circle).

Staghorns in the airport pool bleached each summer as well, and the staghorns spent about as much time bleached as unbleached (Fig. 2). In 2006 and 2008, a period of several weeks of cloudy, rainy, cool weather was followed by a sharp drop in bleaching, and the resumption of normal weather was followed by a resumption of bleaching. Changes in the percentage of corals bleached corresponded closely with nearby ocean SSTs (Fig. 2), appearing to show a rapid, proportional response to warming.

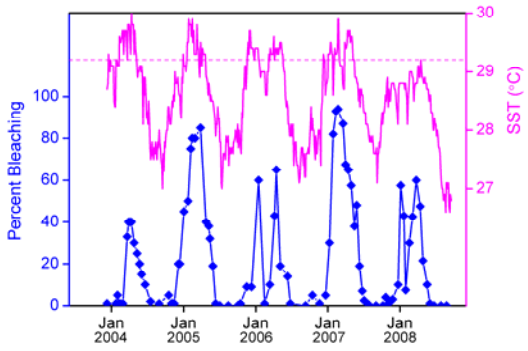

Figure 2 Staghorn bleaching at airport lagoon, Tutuila, and satellite SST. The dashed pink line indicates the temperature of the climatologically warmest month.

Maximum bleaching at the two locations during the five-year period was most often in February with four maximums observed in that month, two in January, two in March, and one in April.

Discussion

Normally, healthy corals show a seasonal variation in the density of their zooxanthellae, with fewer zooxanthellae during the summer and autumn (Fitt et al. 2000). However, healthy corals normally do not loose so many zooxanthellae that they turn white and/or die, so the present observations are beyond the normal range of variation. The pools reached temperatures of about 32 ^{o}C while Fig 2 shows peak temperatures of about 30 ^{o}C for nearby ocean SST's. The fact that *A. nobilis* colonies bleached and partly died in the Alofau pool while the same species at the same depth on the slope about 100 m away did not bleach, indicates that water temperature played an important role in this bleaching, though water motion may well have been a factor as well. The fact that the upper surfaces of staghorns bleached and even died while lower surfaces retained color and survived, is similar to previous reports that upper surfaces of corals bleach more than lower surfaces (Hoegh-Guldberg 1999) and indicates that solar irradiation played an important role in the bleaching as well. This is consistent with the bleaching of the undersurfaces of overturned colonies when other colonies were not bleached, and in addition suggests that upper branch surfaces may have greater resistance to bleaching from irradiation than lower branch surfaces. This pattern is consistent with evidence that bleaching involves the effects of high temperature and irradiation on the photosynthetic system in the zooxanthellae (Coles and Jokiel 1978; Gleason and Wellington 1993; LeTissier and Brown 1996; Hoegh-Guldberg 1999). It is also consistent with reports that previous exposure of coral to bleaching-inducing irradiation can increase resistance to subsequent thermal bleaching (Brown et al. 2000, 2002). The dual roles of irradiation and temperature in bleaching can be captured in the phrase "photothermal bleaching." This also distinguishes this type of bleaching from bleaching produced by other factors, such as darkness, fresh water, or disease. The coral bleaching responded rapidly and proportionately to temperature changes. Maximum bleaching occurred in February, two months after the austral summer solstice, compared to three months after the northern summer solstice in the Caribbean (McWilliams et al. 2005). Thus, bleaching follows peak irradiance and corresponds better to peak SST's in both data sets, indicating that the influence of light is regulated by temperature. Further, there is no sign of the corals developing increasing resistance to

bleaching, even though some in Alofau spend most of the year bleached. However, the low levels of mortality suggest that the corals in these pools may be better equipped to tolerate the effects of bleaching.

Annual summer or autumnal bleaching has been reported in single coral species for *Oculina patagonica* in the eastern Mediterranean (Ainsworth et al. 2007) and *Meandrina meandrites* in Florida (Tichenor 2004). Seven species of intertidal corals have been reported to bleach in Thailand, at least one of which (*Goniastrea aspera*) was documented to bleach annually from solar irradiation (Brown et al. 1994). However, the bleaching of a multi-species coral community in the back reef pools of American Samoa appears to be the first subtidal multi-species bleaching event that appears regularly every summer due to temperature and irradiation. Although this project began at the end of 2003, the fact that bleaching events were reported in 2002 and 2003 indicates that staghorns in the pools very likely have bleached for at least seven years in a row. Such annual bleaching events have been predicted to appear in the future due to global warming (Williams and Bunkley-Williams 1990; Ware 1997; Hoegh-Guldberg, 1999, 2000; Done et al. 2003; Sheppard 2003). These events in the back reef pools of Tutuila may provide insights into the future for coral reefs, and may provide a predictable opportunity to study annual bleaching events and test possible mitigation strategies long before annual summer bleaching becomes common on coral reefs around the world.

1) Department of Systems Ecology, Stockholm University, SE-106 91 Stockholm, Sweden.

Abstract. Global warming and increasing sea surface water temperatures have shown to induce bleaching events and generate phase shifts on coral reefs. Here we investigated the physiological responses (gross primary production, respiration and GP/R ratio) to high temperature (30ºC, i.e. +5ºC above control) and extreme temperatures (34ºC, i.e. +9ºC above control) during 24 hours on one coral species (*Porites lutea*) and five algae species. The result from the organisms' GP/ R ratio showed that only *Sargassum sp.* (*Phaeophyta*) was significantly negatively affected by elevated temperature (34ºC). However, the results showed a positive correlation between the GP/ R ratio and temperature for *Gracilaria asiatica* (*Rhodophyta*). None of the other organisms showed any significant changes in GP/R ratio as a result of treatment. *Asparagopsis taxiformis* (*Rhodophyta*) showed an increase in both gross primary production and respiration. *P. lutea* showed a decrease in both gross primary production and respiration. The physiological responses to increased temperatures differed among the coral reef organisms', even within the same phylum. As a result, this may indicate that the consequences of the imminent global warming may be severe, since it may not only have a negative impact on coral reef organisms directly, but also indirectly, by altering competitive ability between species.

Key words: Increased sea water temperature, physiological responses, algae, *Porites lutea*.

Introduction

Global warming and increasing sea water temperatures have shown to induce bleaching events (Hoegh-Guldberg 1999) and coral mortality (Wilkingson 2004), which furthermore may generate phase shifts on coral reefs (Hughes et al. 2003). In combination with other anthropogenic factors, such as over-fishing (Jackson et al. 2001; Berkes et al. 2006), sedimentation (McCulloch et al. 2003) and pollution (reviewed by Fabricius 2005), this has caused world-wide coral reef degradation (Wilkinson 2000; Jackson et al. 2001).

Coral bleaching causes coral mortality and thereby opens up substratum, which leads to a "window of opportunity" for opportunistic algae to colonize (McClanahan et al. 2001). If herbivores are present they can prevent the algae to overgrow the corals (Hughes et al. 2007). However, if macroalgae successfully establish, a phase shift from coral dominance to macroalgae-dominated state may occur (Done 1992).

On many reefs there have already been transitions from coral dominance to macroalgae dominance due to overfishing of herbivores (Gardner et al. 2003; Hughes et al. 2003; Bellwood et al. 2004). These reefs may therefore lose biodiversity and essential ecosystem services (Nyström et al. 2000) and thus be more vulnerable to climate change (Hughes et al. 2007).

The aim of this study was to investigate the physiological effects of high (30ºC) and extreme temperature (34ºC) increases on one coral species (*Porites lutea*) and five different algae from three different phyla *Ulva compressa, Ulva torta* (*Chlorophyta*), *Gracilaria asiatica, Asparagopsis taxiformis* (*Rhodophyta*) and *Sargassum sp.* (*Phaeophyta*).

Material and methods

P. lutea,, *A. taxiformis* and *Sargassum sp*. were collected at Long Chau Island, Halong Bay (N 20˚ 37' 27", E 107˚ 09' 41") in northern Vietnam. *U. compressa*, *G. asiatica* and *U. torta* were collected in aquaculture ponds close to the lab. Both coral and algae organisms had 72 hours to acclimatize to the lab environment before the experiment started. The experiment was carried out during March 2007 in an outdoor lab at Tram Bien Research Station in Do Son, northern Vietnam.

For the experiment 3 large tanks (1 m^3 each) were used in order to minimise temperature fluctuations (Nyström et al. 2001; Nordemar et al. 2003). In each tank four aquaria (20 l each) were placed. In each aquarium 14 coral pieces or algae tissue were placed

using a randomized block design. During measurements the corals and algae were individually placed in separated transparent jars with air-tight lids, containing 1.5 litre of water each, with the same temperature as the exposure treatments. The three tanks represented: a) control (25ºC), b) high increased temperature (30ºC, i.e. +5ºC above control) and c) extreme increased temperature (34ºC, i.e. +9ºC above control).

In the two exposure tanks, the temperature was increased by applying external heating regulators (ZEBO 300W or FLUVAL Tronic 200W). Aeration pumps mixed the sea water in both the aquaria and the tanks, thus maintaining high oxygen concentrations and distributing water temperature evenly. The experiment was conducted during natural moderate light conditions and the irradiance was 700 (±308) $\mu E/m^2/s$ during the measurements.

The organisms were exposed for 24 hours. Thereafter changes in dissolved oxygen concentration were measured in light (net production) and in darkness (respiration) according to Moberg et al. (1997) using an oxymeter (WTW Oxi 330). To measure the net production, the oxygen level was noted initially and the containers were placed outdoor in full daylight. The oxygen levels were noted again after 30 minutes. To measure the respiration, the organisms were placed in darkness for 30 minutes to adapt to darkness and stop primary production (Moberg et al. 1997), before the initial oxygen value was measured. The oxygen levels were measured once more after 2 hours in darkness.

Before the statistical analyses, the volume of the whole coral was measured by submerging the coral into a beaker filled with a known volume of water, to compensate for volume dependent differences in dissolved oxygen concentration. Thereafter the coral's surface was measured by using the aluminium foil method (March 1970).

Gross primary production rate and respiration rate data were calculated per hour and per cm^2 coral surface area (Moberg et al. 1997) and expressed as O_2 (mg)/h*cm^2. Furthermore, the dry weight of the algae was noted and then the gross primary production and respiration rates were expressed as O_2 (mg)/h*dry weight (g).

For both corals and algae the respiration rate was added to the net production value in order to achieve gross primary production rate (here after referred as gross production). Gross primary production/ respiration (GP/R) ratios were also calculated.

A one-way ANOVA was performed to analyse the effects of treatments for each species. Where the one-way ANOVA showed differences, Tukey HSD was used as a post hoc test ($p<0.05$). To investigate correlations in the data, Pearson correlation test was used. All data were tested for homogeneity of variances using Levene's test ($p<0.05$) before the ANOVA was carried out. For *U. compressa* and *U. torta* only the data from the control and 30ºC treatment group was included in the statistical analysis, since the values from the 34ºC treatment group were considered inaccurate. A t-test was use as a statistical test. For the statistical analyses the software SPSS 13.0 edition for Mac OS X was used.

Results

GP/R ratio

The result from the organisms' GP/ R ratio showed that *Sargassum sp.* was negatively affected by elevated temperature ($p<0.001$, $r=-0.893$ Pearson correlation) (Fig. 1). The 30ºC treatment ($p<0.05$, Tukey HSD) and the 34ºC treatment ($p<0.001$ Tukey HSD) had a lower GP/R ratio compared to the controls (Fig. 1).

For *G. asiatica* the GP/ R ratio showed a trend with a higher GP/R for the algae in the 34ºC treatment group compared to the controls ($p=0.071$ Tukey HSD) (Fig. 1). There was also a positive correlation between the GP/ R ratio and temperature for *G. asiatica* ($p<0.05$, $r=0.488$ Pearson correlation). None of the other organisms (*P. lutea*, *A. taxiformis, U. compressa and U. torta*) showed any variation in GP/ R ratio as a response to high or extreme temperature increase (Fig. 1, 4).

Gross primary production rates

The results from the gross production rates showed that increased temperature had variable effect on the coral and the algae species.

The gross production rate increased significantly with increased temperature in *A. taxiformis*, for both the 30ºC ($p<0.05$ Tukey HSD) and the 34ºC treatment group ($p<0.001$ Tukey HSD) (Fig. 2).

A different result was found in *Sargassum sp*., where the gross production rates decreased in the 34ºC treatment group compared to the control, however this was not significant compared to the controls ($p=0.053$ Tukey HSD). However, the 34ºC treatment group had a lower gross production rate compared to the 30ºC treatment group ($p<0.01$ Tukey HSD) (Fig. 2).

P. lutea showed a lower gross production rate in the 34ºC exposure compared to the controls, however, this was not significant ($p=0.058$ Tukey HSD).

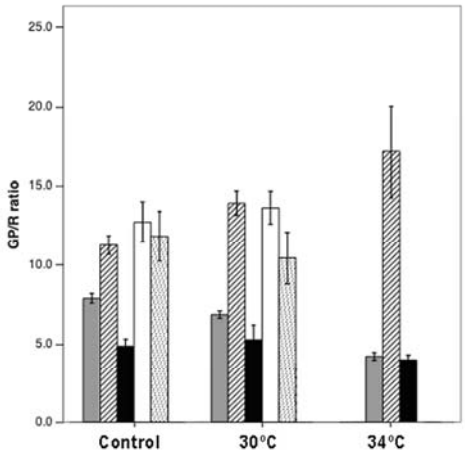

Figure 1: GP/R ratio. *Sargassum sp.* (grey): Control vs. 30ºC *, Control vs. 34ºC ***. *Gracilaria asiatica* (striped): Control vs. 34ºC trend p=0.071. *Asparagopsis taxiformis* (black), *Ulva torta* (white), *Ulva compressa* (dotted): ns. n=7. Error bars: SE.
* p<0.05, *** p<0.001, ns= non significant.

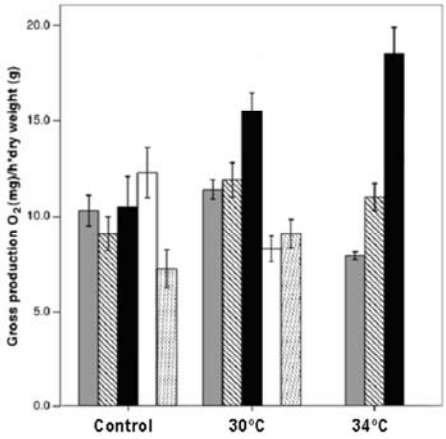

Figure 2: Gross primary production rates. *Asparagopsis taxiformis* (black): Control vs. 30ºC *. Control vs. 34ºC ***. *Sargassum sp*. (grey): Control vs. 34ºC trend p=0.053. 30ºC vs. 34ºC **. *Gracilaria asiatica* (striped), *Ulva torta* (white), *Ulva compressa* (dotted): ns. n=7. Error bars: SE. * p<0.05, ** p<0.01, *** p<0.001, ns= non significant.

Furthermore, there was a significant difference between the higher gross production rate in the 30ºC exposure compared to the 34ºC exposure group (p<0.01 Tukey HSD) (Fig. 4). There were no significant results in gross production rates for *U. torta*, *U. compressa* or *G. asiatica* (Fig. 2).

Respiration rates

Sargassum sp. showed an increase in respiration rate as a reaction to increased temperatures, with a significant difference between the control and the 34ºC exposure group (p<0.01) (Fig. 3).

The respiration rates increased in *A. taxiformis* with temperature and showed a significant difference between the control and the higher respiration value in the 34ºC treatment group (p<0.001), there was also a trend for an increase in respiration in the 30ºC treatment compared to the control (p=0.051) (Fig. 3).

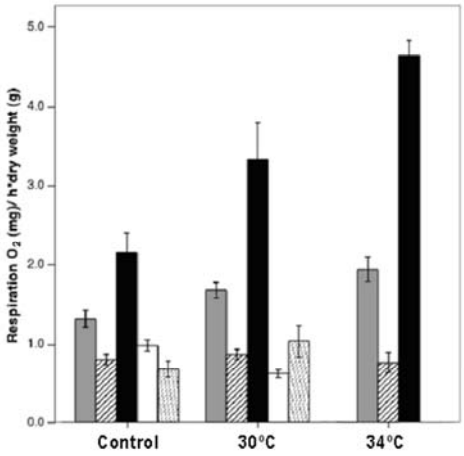

Figure 3: Respiration rates. *Sargassum sp.* (grey): Control vs. 34ºC **. *Asparagopsis taxiformis* (black): Control vs. 30ºC trend p=0.051. Control vs. 34ºC ***. 30ºC vs. 34ºC *. *Ulva torta* (white): Control vs. 30ºC **. *Gracilaria asiatica* (striped), *Ulva compressa* (dotted): ns. n=7. Error bars: SE. * p<0.05, ** p<0.01, *** p<0.001, ns= non significant.

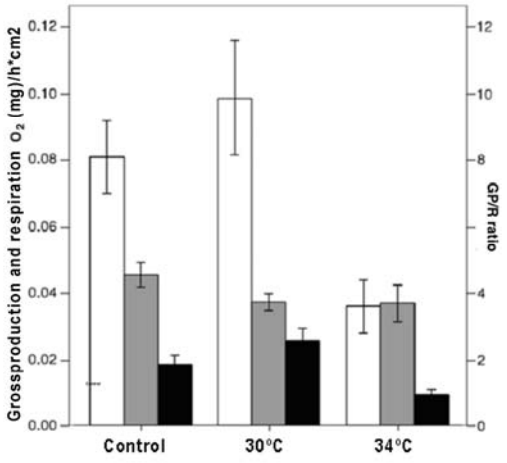

Figure 4: GP/R ratio, gross primary production and respiration rates for *Porites lutea*. Gross primary production (white): Control vs. 34ºC trend p=0.058. 30ºC vs. 34ºC **. Respiration (black): Control vs. 34ºC trend p=0.082. 30ºC vs. 34ºC **. GP/R ratio (grey): ns. n=7. Error bars: SE. ** p<0.01, ns= non significant.

Furthermore, the 34ºC treatment had a higher respiration compared to the 30ºC treatment (p<0.05) (Fig. 3). *U. torta* showed a decrease in respiration rates between the control and the 30ºC treatment group (p<0.01) (Fig. 3).

The respiration rate for *P. lutea* in the 34ºC treatment group was lower than both the control ($p=0.082$) and the 30ºC treatment group ($p<0.01$) (Fig. 4).

No significant differences could be found in *G. asiatica* or *U. compressa* (Fig. 3).

Discussion

Several authors have reported that increased temperature may have a negative effect on corals (Coles and Jokiel 1977; Fitt and Warner 1995; Hoegh-Guldberg and Smith 1989; Nyström et al. 2001). However, studies have shown a positive correlation between increased temperature and GP/R ratio in algae (Elwing and Tedengren 2000) and increased algae biomass (Tsai et al. 2005).

The results from the study showed dissimilar responses in GP/R ratio to elevated temperature for the algae species. *Sargassum sp.* was negatively affected by increased temperature, which was reflected in a decrease in GP/R ratio. In the field, Ateweberhan et al. (2005) showed that the highest growth rate for *Sargassum sp.* occurred at 28-30ºC, while the growth rate was below zero when the temperature reached 33-36ºC. Furthermore, *Sargassum sp.* has shown to be a late succession species (Hughes et al. 2007), which establish after green filamentous algae (Kokita and Nakazono, 2001), such as *Enteromorpha* (McClanahan 1997). Our results showed that neither *U. torta* nor *U. compressa* was negatively affected by a high increase in temperature. This suggests that increased sea water temperature may have a limited effect on early succession algae species, which may or may not be followed by a succession of brown frondous algae.

In contrast to *Sargassum sp.*, *G. asiatica* was positively affected with an increase in GP/R ratio, in response to elevated temperature. A decrease in gross production rate together with an increase in respiration rate explained the changes in GP/R ratio for *Sargassum sp.*, while the result for *G. asiatica* was explained by a stimulated gross production rate whereas no change in respiration was noted. A positive relationship between temperature and growth rate for *Gracilaria coronopifolia* has been found by other authors (Tsai et al. 2005). Furthermore the results showed that *A. taxiformis* increased both gross production and respiration rates due to the temperature treatment, however the GP/R ratio was not affected. This in turn might indicate higher metabolic requirements and energetic costs due to thermal stress (Bayne et al. 1985). On disturbed coral reefs, *Asaparagopsis taxiformis* may completely dominate the reef and form large canopy (Diaz-Pulido and McCook 2002), which, especially in the absence of herbivores, may prevent corals to re-establish after disturbances (Hughes et al 2007).

In this study *P. lutea* did not show any changes in GP/R ratio due to heat treatment. Nevertheless, both gross production and respiration rates were affected, indicating that increased temperature had an effect on the coral's metabolism, at least to some extent.

A possible explanation to these results may be that the corals in the region may be adapted to large variation in seasonal temperature, as has been noted in other regions (Kemp et al. 2006), since the water temperature may fluctuate between 16ºC and 31ºC in the Halong Bay area during the year (Nguyen 2004; Latypov 2005). Upper thermal limits have been shown to vary between the same coral species in different regions (Hughes et al. 2003), suggesting that local adaptation may occur (Cook et al. 1990).

Furthermore, *P. lutea* has been shown to be tolerant to elevated temperatures and has been known to prevail during bleaching events (Loya et al. 2001; Baker et al. 2004; McClanahan et al. 2007). Nevertheless, our results suggest that since increased temperature in fact benefited several of the algae species, but had a limited effect on *P. lutea*, this may alter the competition between the species.

The results from this experiment demonstrate that coral reef organisms' physiological responses to increased temperatures vary between species, even within the same phylum. This in turn suggests that the consequences of global warming may be severe, since it not only will affect coral reef organisms directly, by reduced metabolism/growth rate and increasing mortality, but also indirectly by altering their relative competitive ability, which in turn may lead to decreased biodiversity and an increase in coral reef vulnerability to further anthropogenic or natural disturbances.

In addition, during periods of elevated temperatures, this could have further implications. If several species of algae may in fact be positively affected by elevated temperatures this may lead to a more rapid overgrowth of algae after e.g. bleaching events, and thereby contribute to a phase shift, especially in areas where herbivore fish and invertebrates are more or less absent, due to over-exploiting of marine resources.

Reef development and resilience to acute (El Niño warming) and chronic (high-CO_2) disturbances in the eastern tropical Pacific: a real-world climate change model

Abstract It has been recently recognized that eastern tropical Pacific (ETP) coral reefs exist under naturally-occurring high-CO_2, low carbonate saturation (Ω) conditions that encompass the range of expected changes for the entire tropical surface ocean with a doubling and tripling of atmospheric CO_2. Holocene reef development positively and linearly tracks Ω in the ETP; illustrating the real-world importance of this variable on reef building. Galápagos reef communities have been subject to the most extreme thermal anomalies associated with the El Niño-Southern Oscillation (ENSO) and also experience the lowest Ω levels in the ETP. Reef resilience has been so poor in Galápagos that reef structures were completely bioeroded in < 10 years after the 1982-83 ENSO. The closure of the Panamanian isthmus 3-3.5 million years ago created the present-day oceanographic conditions responsible for ENSO-related warming events and the upwelling of high-CO_2 waters throughout the ETP. These combined acute (ENSO) and chronic (high-CO_2) disturbances may help explain why coral reefs are scant and many genera of corals went extinct in the ETP during the late Cenozoic; thus providing a real-world example of the combined thermal and chemical ramifications of climate change on coral reef structure, function and resilience to disturbance over geologic time.

Introduction

Coral reefs flourish in the tropics where temperatures are warm year-round (> 18°C), illumination is high/turbidity is low, and seawater is supersaturated with respect to calcium carbonate ($CaCO_3$) (Kleypas et al. 1999a). Considerable environmental variability has been recognized as detrimental to coral reef development since Charles Darwin's (1842) original treatise on the subject. The relative importance of the specific environmental variables eliciting this distributional hypothesis is less obvious. Elevated nutrients have been hypothesized to be particularly deleterious to coral reef development based upon the assumptions that nutrients stimulate water-column productivity and turbidity, thus limiting the light required by the photosynthetic endosymbionts of reef corals (Hallock 1988) (Fig. 1). Increased levels of nutrients and productivity are thought to favor the proliferation of fleshy benthic macroalgae (autotrophs) and heterotrophic communities (e.g. filter-feeding bioeroding organisms), respectively, at the expense of "mixotrophic" community assemblages like that of modern-day Scleractinian coral reefs (Hallock and Schlager 1986) (Fig. 1). Also, Hallock and Schlager (1986) suggested that high concentrations of phosphate inhibit coral calcification given its potential to act as a poison to crystal formation (Simkiss 1964).

However, nearly all the evidence supporting this hypothesis is qualitative (e.g. Hallock and Schlager 1986; Hallock 1988) or high nutrient exposure experiments only elicit significant results on coral calcification at concentrations that would rarely, if ever occur in nature (Kinsey and Davies 1979; Ferrier-Pagès et al. 2000). Coral reefs do, in fact, persist under wide ranges of nutrients and turbidity (Smith and Jokiel 1978; Perry et al. 2008) and even reef areas thought to be oligotrophic experience variable and sometimes high levels of dissolved nutrients due to natural physical forcing mechanisms (Leichter et al. 2003). Several recent review papers have pointed out the tenuous links between nutrients, algal competition and coral reef decline (McCook et al. 2001; Szmant 2002). As Tomascik and Sander (1985) suggested, it is likely that nutrients themselves do not elicit the most negative effects *per* se, but rather the increase in water-column productivity, turbidity and accompanying decline in light levels

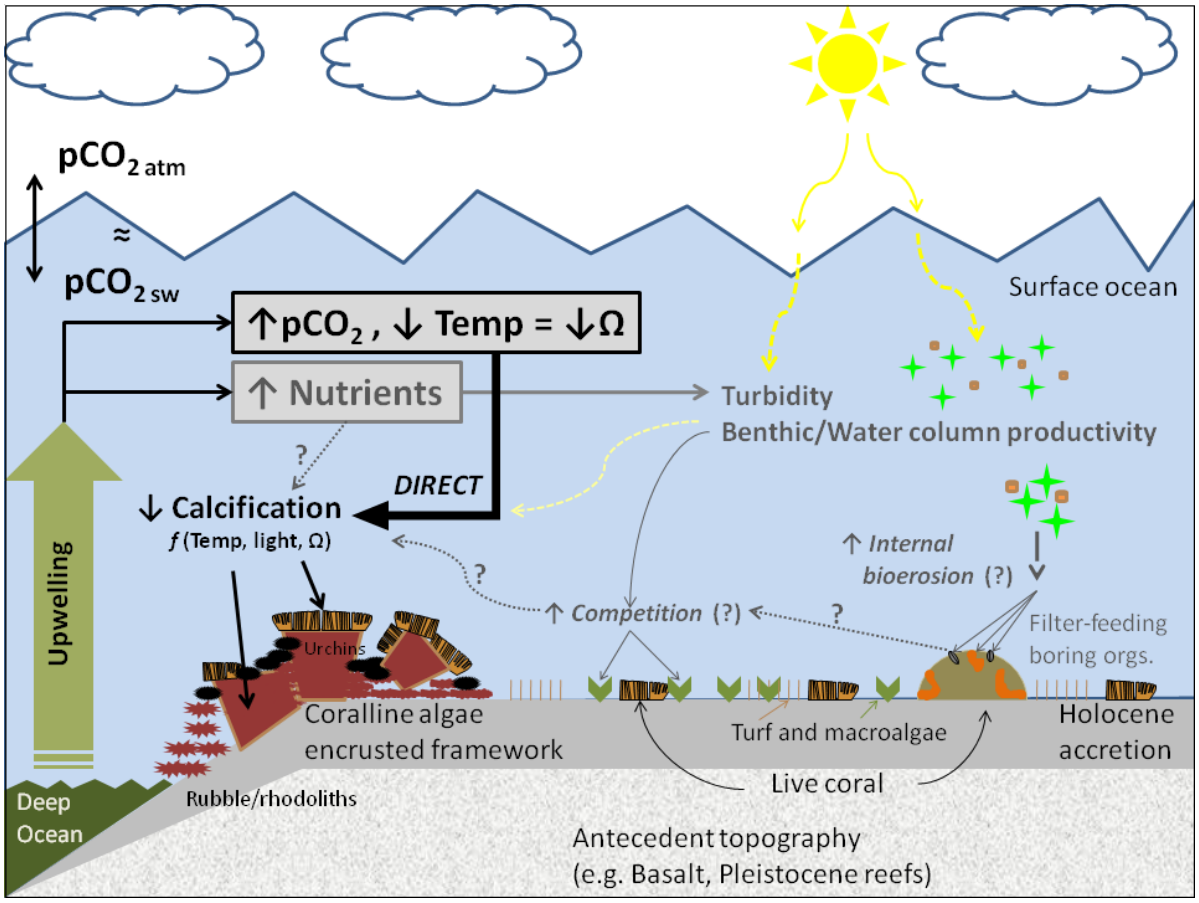

Fig. 1. Simplified model illustrating direct effects of high-pCO_2, low-Ω seawater on reef-building in an upwelling environment compared to primarily indirect effects of elevated nutrients (Smith and Buddemeier 1992).

that are associated with nutrient inputs (natural and anthropogenic) are most deleterious for reef corals.

Upwelling and reef development in the eastern Pacific

Upwelling areas experience highly heterogeneous environmental conditions that experience not only wide ranges in temperature, nutrients and turbidity, but recently it has been recognized that upwelled waters have a high partial pressure of carbon dioxide (high-pCO_2) (Takahashi et al. 1997). This high-pCO_2 effectively depresses the saturation state of $CaCO_3$ ($\Omega = [Ca^{2+}][CO_3^{2-}]/K'_{sp}$, where K'_{sp} is the solubility product of a carbonate mineral such as aragonite or calcite), which is a function of both CO_2 and temperature. Indeed, surface waters in many parts of the eastern tropical Pacific (ETP) have lower pH, lower Ω, and higher pCO_2 values relative to the rest of the tropics (Manzello et al. 2008). Given that depressed Ω and temperature elicit a direct negative effect upon coral calcification and reef building (Langdon et al. 2000), it is hypothesized that these two variables may be just as, if not more responsible than nutrients for the paucity of reef development in upwelling zones.

The intensity of upwelling varies regionally and strongly influences reef development across the ETP (Cortés 1997). High-CO_2, low-Ω influenced coral reefs of the ETP are poorly cemented accretions of $CaCO_3$ that are subject to rapid bioerosion (Manzello et al. 2008; Fig. 2a). The thickness of these reefs reflects Ω in a positive, linear fashion (Fig. 3), illustrating the net result of coral calcification ($CaCO_3$ production) minus its loss (erosion) over geologic time. Fig. 3 illustrates the extent of reef framework accumulation across a naturally-occurring gradient of seawater chemistry, but does not imply a direct cause and effect relationship as there are several additional physical variables that significantly influence reef growth and development such as temperature, light, shelf-area, and antecedent topography (Macintyre et al. 1992). Despite these caveats, it can be reasonably deduced that the effects of high-CO_2 most clearly manifest over geologic time-scales in the processes of reef framework development, preservation potential, and persistence (reef cementation: Manzello et al.

2008; framework accumulation: Fig. 3), rather than in the readily observable biological phenomena on the reef surface.

Ocean acidification and global warming analogs in the eastern Pacific

Anthropogenic forced climate change models predict continued and accelerated global warming due to rising concentrations of CO_2, primarily from the unregulated combustion of fossil fuels since the industrial revolution (IPCC 2007). Global mean surface temperature has increased approximately 0.74°C in the past 100 yrs and is expected to increase by no less than 1.5°C further by the year 2100 (IPCC 2007). Proposed increases in temperature are of concern because reef-building corals live at or near their upper thermal limits as positive temperature anomalies of as little as 1°C sustained for one month during the warmest part of the year have been shown to correlate with mass-coral bleaching events (Glynn 1993; Goreau and Hayes 1994; Brown 1997).

An estimated one-third of all the CO_2 released into the atmosphere since the industrial revolution has been absorbed by the oceans (Sabine et al. 2004). This ongoing and accelerating uptake of atmospheric CO_2 is causing a drop in seawater pH at the global scale (Orr et al. 2005), resulting in an acidification of the surface ocean (Caldeira and Wickett 2003). Ocean acidification results in a decrease in seawater $[CO_3^{2-}]$ and, consequently, a decrease in the saturation state (Ω) of carbonate minerals (Kleypas et al. 1999b). Acidification is expected to reduce coral reef calcification and increase reef dissolution, and the relative rates of change will likely be a function of pCO_2 in surface seawater, which is near equilibrium with pCO_2 in the atmosphere (Smith and Buddemeier 1992; Kleypas et al. 1999b; Langdon et al. 2000; Yates and Halley 2006). Carbonate budget studies have shown that healthy coral reefs exhibit low net accretion due to high rates of physical, chemical and biological erosion (reviewed by Glynn 1997a). Consequently, any disturbance that causes either decreased accretion or increased erosion may tip the tenuous balance from reef framework growth to loss.

The carbonate chemistry of seawater influencing reef sites in the Galápagos and Gulf of Panamá is similar to what is expected for the average tropical surface ocean with a doubling and tripling of atmospheric CO_2, respectively (Fig. 3). Thus, the response of these reef communities to the El Niño-Southern Oscillation (ENSO) provides a real-world example of what may be the future for coral reefs globally with accelerating climate change.

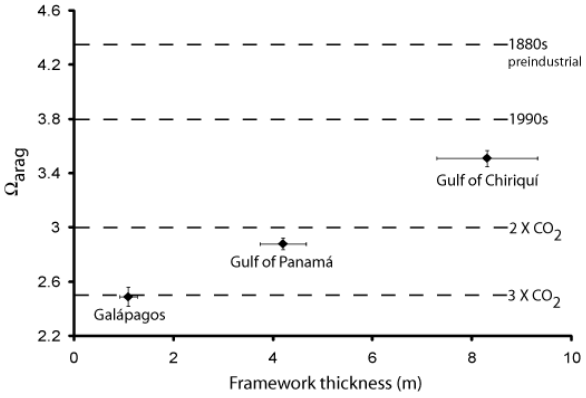

Fig. 3. Mean maximum reef framework thickness (m, ±SEM) from eastern tropical Pacific relative to the saturation state of aragonite, Ω_{arag}. Aragonite is the type of $CaCO_3$ deposited by Scleractinian corals. Ω_{arag} values measured in ETP and estimated for average tropical surface ocean with differing levels of atmospheric CO_2 calculated as described in Manzello et al. (2008). Framework thicknesses of all pocilloporid reef sites prior to the 1982-83 ENSO in Galápagos and Panamá originally presented by Glynn and Wellington (1983) and Glynn and Macintyre (1977), respectively.

Galápagos coral reef communities experienced a greater and longer thermal anomaly (3-4°C for several months) associated with the 1982-83 ENSO in comparison to those in Pacific Panamá (1-2°C for two months) (Podesta and Glynn 1997). As a result, coral mortality from prolonged bleaching was greater in Galápagos (97-99%) compared to Panamá (75-85%; Glynn 1990). Following this mass mortality, reef framework structures in Galápagos were rapidly and completely bioeroded to rubble and sand in less than a decade and are now non-existent (Glynn 1994; Reaka-Kudla et al. 1996; Fig. 2b-d). Conversely, reef framework structures have persisted in Panamá despite evidence of net erosion following two severe

ENSO events (Eakin 2001). The rapid destruction and disappearance of Galápagos reefs is the end result of several cascading factors that include the extreme thermal anomaly/resultant mass mortality, less pre-existing amounts of reef framework compared to Panamá, a population explosion of bioeroding echinoids, and poor recruitment potential (Glynn 1994). However, the impact of high-CO_2, low-Ω seawater on carbonate cement precipitation and its apparent inverse relationship to bioerosion rate in the ETP adds a key piece to the puzzle as to why reefs throughout the ETP are poorly developed and ephemeral on geologic time-scales (Manzello et al. 2008).

Durham's dilemma revisited

The closure of the Panamanian isthmus 3 to 3.5 million years ago established the present-day oceanographic conditions (Keigwin 1982) necessary for ENSO-related climate phenomenon (Colgan 1990). These oceanographic conditions also established the chronic upwelling of high-CO_2, sub-thermocline waters to the surface layers throughout the ETP (Keigwin 1982; Takahashi et al. 1997; Manzello et al. 2008). Even where ETP reefs are best developed in the Gulf of Chiriquí off Panamá, the signature of these high-CO_2, low-Ω waters is evident at shallow depths (Table 1). These significant decreases in Ω, temperature, and increases in turbidity and nutrients at shallow depths illustrate why reefs are generally restricted to very shallow depths (< 10 m) throughout the ETP (Dana 1975; Glynn and Maté 1997; Cortés 1997; D'Croz and O'Dea 2007).

Table 1. Carbonate parameters measured *in situ* at surface (n = 82) and 15 m depth (n = 13) at the Uva Reef, Gulf of Chiriquí, Panamá. Values represent means (±SEM) of samples taken during both wet and dry seasons over four consecutive years (2003-2007).

Depth	TCO_2 (μmol kg^{-1})	TA (μmol kg^{-1})	pH (sws)	pCO_2 (μatm)	Ω_{arag}	T (°C)
< 5 m	1795.3 (9.27)	2089.6 (8.45)	8.01 (0.01)	406 (14.1)	3.51 (0.06)	28.9 (0.11)
15 m	1931.0 (18.8)	2187.5 (15.4)	7.96 (0.012)	480 (16.5)	3.05 (0.09)	25.9 (0.77)
†P	***	***	*	**	**	***

†-Probability that two distributions were not significantly different using Mann-Whitney U-tests (P < * = 0.01, ** = 0.001, *** < 0.0001). TCO_2, TA and *in situ* temperature measured and CO_2-system calculated as described in Manzello et al. (2008).

J. W. Durham (1966) posited two questions, later referred to by Glynn (1997b) as 'Durham's dilemma', related to the depauperate state of coral reefs in the far eastern Pacific: (1) Why are coral reefs absent during the late Cenozoic and (2) why did so many genera of corals go extinct in the ETP during the Cenozoic, but continue to persist in other areas? Glynn (1997b) suggested that the ENSO-induced thermal anomalies that can elicit mass-mortalities, severe population reductions, and extirpations of reef corals throughout the ETP were likely a pivotal element towards resolving this dilemma.

Veron (2008) recently hypothesized that perturbations to the global carbon cycle and ocean acidification provide an explanation for past episodes of reef-building extinction (i.e. reef gaps) in the geologic record. The interaction of oceanography, biology, and geology in response to ENSO across the ETP illustrates one mechanism for the cessation of reef-building and destruction of reef structures.

The chronic influence of these previously unappreciated low-pH, low-Ω, and high-pCO_2 waters acting in concert with periodic, acute ENSO-associated thermal anomalies may provide an answer to Durham's dilemma while simultaneously granting a real-world model for the combined thermal and chemical ramifications of climate change on coral reef structure (Manzello et al. 2008), function and resilience to disturbance over geologic time.

Bleaching as a life history trait in coral-zooxanthellae holobionts – relevance to acclimatization and adaptation

D.O. Obura

CORDIO East Africa, P.O.BOX 10135, Mombasa 80101, Kenya. dobura@cordioea.org

Abstract. This paper explores the relationship between bleaching patterns and growth strategies of coral-zooxanthella holobionts in relation to tradeoffs in benign and stressful environments. Growth strategies can be differentiated between growth/production maximizing versus stress tolerating/persistent options. The former are dependent on high growth (or reproductive) rate for competitive success and extension over space; their tradeoff is a high opportunity cost of reducing production, i.e. of an adversity response when stressed. The latter are dependent on their ability to persist under adverse conditions to maintain control over space; their tradeoff is low performance under good conditions. Obura's (2009) model for stress resistance in corals predicts that bleaching is induced under stressful conditions to reduce excess production by zooxanthellae and thereby maintain symbiotic balance. This hypothesis is consistent with bleaching responses where corals that invest in rapid growth (/reproduction) tend to bleach and die at lower levels of stress (e.g. *Acropora, Pocillopora*), while corals that invest in stress resistance tend to bleach and survive at higher levels of environmental stress (e.g. *Porites*). These bleaching/life history strategy patterns shed light on the scope for acclimatization and adaptation of corals, independently of the multiplicity of mechanisms that are precursors to the bleaching response.

Keywords: bleaching, symbiosis, scleractinian coral, zooxanthellae, climate change, environmental stress

Introduction

Obura (2009) presents a model for coral bleaching that reconciles the adaptive role of bleaching (Fautin and Buddemeier 2004) with the many competing interpretations of bleaching in the literature (Hoegh-Guldberg 2005) (Fig. 1). The model is based on life history tradeoffs between fast growth and reproduction versus stress resistance and persistence (Grime 1977, Stearns 1989, Greenslade 983) and interpretation of bleaching as a Stress Response Syndrome (SRS) or General Adaptive Mechanisms (Stebbing 1981).

The model is based on the premise that the life history strategies of the space-dominating (e.g. *Acropora*) and opportunistic strategies of small branching (e.g. pocilloporid) corals require high investment in maintaining high photosynthetic activity by zooxanthellae and consequently high metabolic activity of the holobiont to utilize and manage this energy. Conversely, the stress tolerant strategies characterized by large long-lived massive (e.g. *Porites*) and many small slow-growing (e.g. *Siderastrea*) corals require commitment to an adversity response to stress, i.e., the ability to survive at low metabolic levels during stress to

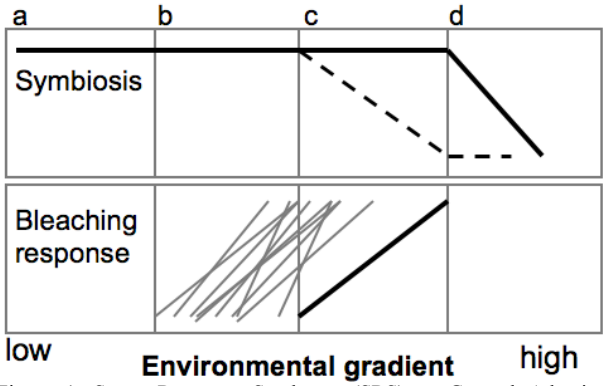

Figure 1. Stress Response Syndrome (SRS) or General Adaptive Mechanism (GAM) model (Stebbing 1981) for coral bleaching (Obura 2009). The intact symbiosis is maintained in balance (panels a-c, top) by homeostatic control mechanisms, but declines to zero (mortality, panel d) when the control mechanisms are exhausted. At low levels of stress a variety of first order stress responses (e.g. photo-chemical quenching, induction of heat shock proteins) sensitive to environmental stimuli (grey lines, panel b, bottom) may be induced, depending on the external stress. Once their tolerance range (counteractive capacity) is exceeded a second order control system sensitive to internal stress, the bleaching response, is activated (panel c, bottom), during which coral colour decreases (dotted line, top panel), but the symbiosis is intact and health (solid line, panel c, top). Once the maximum threshold for bleaching is exceeded, homeostasis is impaired, and the holobiont begins to break down irreversibly (panel d). Adapted from Obura (2009).

Table 1. Life history strategies based on the primary literature on animals and plants, and observational/empirical strategies described for stony corals.

Equilibrium/Competitive	*Opportunistic/Ruderal*	*Persistence/Adversity*	*Source(s)*
Primary models			
Density dependence, low rates of increase, thrive in predictable conditions.	Density independence, high rates of increase, thrive in unpredictable conditions.	Adaptation to predictably unfavourable environments. Slow rates of increase, low abundance, persistence.	MacArthur 1960, Pianka 1970, Greenslade 1983
Highly competitive, large size, fast growth.	Opportunistic, small size, fast growth, ephemeral.	Stress-tolerant, varied growth forms, slow growth, long lifespan.	Grime 1977
Empirical coral models			
N/a	Opportunistic, fast growth rates, high sexual and/or asexual reproduction, monopolize space in short term. High turnover. *Acropora, Pocillopora*.	Adaptations to low abundances, persistence through varied environmental conditions. *Porites*.	Cameron and Endean 1990
Branching, high reproductive output (spawners), low recruitment, high survivorship of juveniles, high fragmentation, high regeneration fast growth rates, long-lived but with senescence. *Acropora*.	Foliaceous/branching, high recruitment, fast growth, high tissue turnover, high partial and full mortality, small adult size, low competitive abilities, low regenerative abilities. Small agariciids, pocilloporids.	Massive, low recruitment, high survivorship, slow growth, low partial mortalit, fragmentation important, long life expectancy, low tissue turnover, large adult size, competitively aggressive, resistant to sediment , high regeneration. *Montastrea annularis, Porites*	Bak and Engel 1979, Jackson and Hughes 1985, Kojis and Quinn 1994

endure it until conditions improve (Greenslade 1983, Hoffman and Parsons 1991). These expectations are consistent with predictions of life history theory (Stearns 1992), which distinguishes between strategies that maximize or invest in growth and/or reproduction (production) vs. those that maximize survival through stress resistance (persistence). These strategies impose opposite constraints on many organismal processes, and require investments from a limited resource base (Stearns 1989). In the terms of the two main strategy concepts explored in the plant and animal literature – the r-K theory of Macarthur (1960), and the CSR theory of Grime (1977), these can be expressed as opposite responses with respect to energetic investment of the life history strategy – high-energy investment in rapid growth and dominance of space – K or C strategies, and/or high levels of reproduction – r or R strategies, and low-energy investment in longevity – K, or stress resistance – S strategies.

The literature on coral life history strategies has focused on life history traits such as recruitment rate, growth rate, colony size, colony morphology, longevity and reproductive strategies, with authors variously identifying 2 or 3 basic strategies (Table 1). Obura (2001) interpreted these with respect to bleaching patterns to distinguish the high-energy and low-energy options above, but an explanatory framework explaining why this should be so has been lacking. Obura (2009) proposes bleaching as a last-resort mechanism that the coral-zooxanthellae holobiont uses to manage energy relations consistent with the above strategies, and this paper explores this framework for understanding variability in bleaching patterns across taxonomic, spatial and temporal domains.

Methods

The hypothesized role of bleaching is to slow down zooxanthellar photosynthesis as an adversity response under stress, acting as a Stress Response Syndrome or General Adaptive Mechanism (Stebbing 1981). Explicit gene-environment interactions and selective pressures on bleaching as an SRS/GAM can be deduced and tested, against predictions for growth/reproduction or stress resistance based on life history theory (Stearns 1992). In scleractinian corals, growth and reproductive output are determined by zooxanthellae production and translocation rates, as these are energy intensive processes. Thus a direct relation between bleaching and reduced growth/reproduction can be inferred and used to interpret tradeoffs in life history strategies between high production (growth, reproduction) vs. stress resistance (persistence, adversity).

The paper will analyze hypothetical changes from a baseline state of a coral-zooxanthellae holobiont in the parameters of the bleaching response – the induction and maximum thresholds and counteractive capacity. Two basic responses of the bleaching parameters will be explored:

A. Linear shifts up and down the stress gradient of induction and maximum thresholds, maintaining constant counteractive capacity (slope and range from induction to maximum), and
B. Non-linear shifts up and down the stress gradient of induction and maximum thresholds, resulting in varying counteractive capacity, of the bleaching response.

These changes represent selective pressures imposed by environmental conditions on different life history strategies, and the hypothesized impacts on bleaching and holobiont survival will be analyzed for consistency with field observations and life history theory.

Results

A linear shift up or down the environmental axis, of both induction and maximum bleaching thresholds results in no change in the slope of the response, and no change in its counteractive capacity (Fig. 2a, Table 2). The resulting new bleaching responses are therefore:

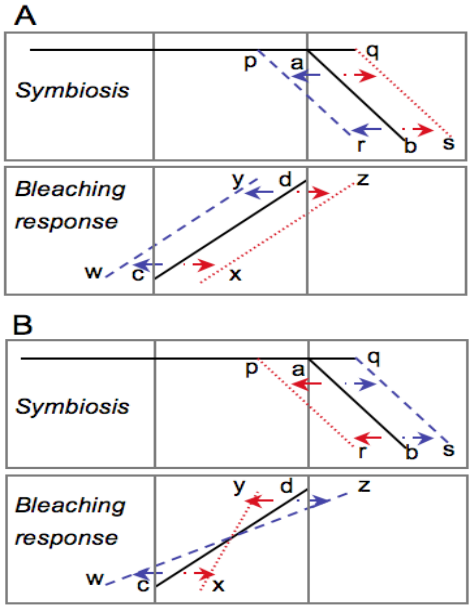

Figure 2. Bleaching response and symbiosis state – linear (A) and non-linear (B) shifts in response thresholds. Solid lines represent intial state, dotted lines are adaptive responses, see text and Table 2 for details.

Table 2. Summary of bleaching response and symbiosis states from Fig. 2, and see text for details.

Bleaching response	Symbiosis state	Growth rate	Stress resistance	Response shift
w-y	p-r	slow	low	Linear
x-z	q-s	fast	high	Linear
x-y	p-r (<r?)	fast	low	Narrowed?
w-z	q-s (>s?)	slow	high	Broadened?

- down-shift on the environmental axis (bleaching response c-d to w-y; symbiosis response a-b to p-r). The effect of this is less growth (earlier shut-down of maximum growth at w-y vs. c-d) and lower resistance to environmental stress (bleaching and mortality at lower levels of external stress p-r vs. a-b).
- up-shift on the environmental axis (bleaching response c-d to x-z; symbiosis response a-b to q-s). The effect of this is more growth (later shut-down of maximum growth at x) and higher resistance to environmental stress (bleaching and mortality at higher levels of external stress x-z vs c-d and q-s vs. a-b).

Linear shifts in the bleaching response thus result in high growth-high stress resistance (x-z/q-s) and low growth-low stress resistance (w-y/p-r) strategies. Applied to a hypothetical environment (Fig. 3), the linear shifts correspond to shifts between the paired induction/maximum thresholds A-C and B-D.

Non-linear shifts up or down the environmental axis, of induction and maximum bleaching thresholds result in changes in the slope of the bleaching response, i.e. a change in the counteractive capacity (Fig. 2b, Table 2). The simplest non-linear responses are:

- down-shift of the bleaching induction threshold (c to w) paired with no change or up-shift in the maximum threshold (stable at d, or d to z). The effect of this is less growth (earlier shut-down of maximum growth at w) but a broader counteractive capacity, w-d or w-z, and potentially higher resistance to environmental stress if the maximum threshold increases to z. The corresponding symbiosis shift is from a-b to p-b, or to p-s.
- up-shift of the bleaching induction threshold (c to x) paired with no change or down-shift in the maximum threshold (stable at d, or d to y). The effect of this is more growth (later shut-down of maximum growth from c to x) but a narrower counteractive capacity, x-d, and potentially less resistance to environmental stress if the maximum threshold is reduced, x-y. This reduction in the maximum threshold may happen as a result of higher stress due to greater internal metabolic imbalance at the higher environmental stress levels. The corresponding symbiosis response is p-b, or even p-r.

Non-linear shifts in the bleaching responses, result in high growth-low stress resistance (x-y/p-r) and low growth-high stress resistance (w-z/q-s) strategies. Applied to a hypothetical environment, the non-linear shifts correspond to paired induction/maximum thresholds A-D and B-C (Fig. 3).

Other non-linear shifts may be possible, however these can all be expressed as variants on the above two options based on whether the bleaching response curves intersect (basic non-linear response above) or not (basic linear response above).

Discussion

The selective pressures that result in non-linear shifts can be described as follows. A shift in the induction threshold for bleaching, from c to w or x will result in earlier and later induction of bleaching (respectively). If environmental stress stays within that range, then a species with threshold x will always outcompete a species with threshold w, as all other things being equal, growth of species “x” will be unimpaired by bleaching, while growth of species “w” will decrease due to lower zooxanthellae density and production once c has been crossed. If there is no change in the maximum threshold

for bleaching, d, then species x-d will always outcompete species w-d. This effect would be increased if a linear shift (Fig. 2a) were to occur (i.e. x-y and x-z, respectively). Such shifts are incompatible with life history theory as tradeoffs in resource allocation prevent positive correlation between high growth and stress resistance (Stearns 1989, Hoffman and Parsons 1989). In any community if there is a species or genotype that could grow fastest and always resist stress, it would always dominate.

Tradeoffs imposed by life history options require that shifts in the bleaching induction threshold up or down are complemented by an opposite shift in the maximum thresholds, such that the species with induction threshold x will tend towards maximum threshold y and species with induction threshold w will tend towards maximum threshold z. This allows for a change in competitive advantage between the species once the environmental stress has exceeded the point at which the bleaching responses intersect (Fig. 2b). Below the intersection the fast-growing species x-y will dominate, but above the intersection the stress resistant species w-z will dominate.

Growth/production maximizers (x-y/p-r)

These species will tend to maximize utilization by the host of fixed products from the zooxanthellae and may also include maximization of production by zooxanthellae. They are dependent on their high growth (or reproductive) rate for competitive success and extension over space. Their tradeoff is a high opportunity cost of reducing production. Thus they may adapt to raise the induction threshold of their bleaching response to postpone decreased production. If conditions deteriorate further, bleaching will occur, and it is possible that tissue damage may be higher as a result of the raised induction threshold and higher levels of internal metabolic stress. This raised internal stress may narrow the counteractive capacity, effectively lowering the maximum threshold and bringing on earlier collapse of the symbiosis.

In a model environment, growth/production maximizers will have induction and maximum bleaching thresholds at B and C, respectively (Fig. 3). If environmental conditions stabilize before the induction threshold (E1), or perhaps at mid-levels in the bleaching response, the strategy is successful. However the lowered maximum threshold means they are more vulnerable where conditions do not improve or in highly fluctuating environments (E2) so have a high risk of mortality. These species thrive and dominate space in habitat E1, outcompeting other species, but suffer high mortality in E2.

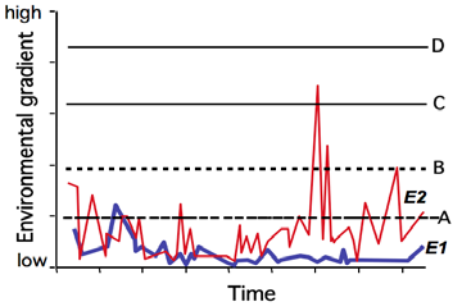

Figure 3. Environmental variability in benign (E1) and extreme (E2) habitats over time. Induction (horizontal lines A, B) and maximum (C, D) thresholds of a bleaching stress response (see Fig. 2) are shown. See discussion for details.

Stress tolerators/persisters (w-z/q-s)

These species will tend to minimize overall metabolism and therefore also production by zooxanthellae, and emphasize efficient use or management of fixed products by the host. They are dependent on their ability to persist under adverse conditions to maintain their space. Their tradeoff is low performance under good conditions. With a low opportunity cost of reducing production, early response to stress may develop. If this decreases the buildup of internal stress it may have the effect of broadening the range over which bleaching occurs, raising the maximum threshold that can be tolerated. This will further broaden the counteractive capacity and delay collapse of the symbiosis.

In a model environment, stress tolerators will have induction and maximum bleaching thresholds at A and D, respectively (Fig. 3). Under consistently benign conditions (E1), they cannot compete with production maximizers as they grow slower, and suppress growth at lower environmental stress levels. However, their higher maximum thresholds mean the can persist in widely fluctuating habitats (E2), with a low risk of mortality. These species persist in habitat E2, but are outcompeted by other species in E1.

These strategy descriptions fit classical life history strategies, both for r/K strategies and C-S-R strategies (Table 1), with the caveat that competitive and opportunistic strategies are both high growth/high risk strategies, but are optimized to different environmental conditions. With respect to bleaching and thermal stress, differences between ‘winners and losers’ have been described (e.g. Loya et al. 2001), explained by aspects of gross morphology, such as colony shape and tissue thickness. The analysis here offers an alternative framework based on metabolic rates and growth/resistance strategy, and further research may be able to show if growth form and other variables may be correlates or secondary to these. Certainly growth form

Table 3. Bleaching strategies summarized from Obura (2001) applied to life history strategies discussed in this paper.

Bleaching strategy	High bleaching/high growth	Variable bleaching/mortality	Persistent bleaching/low mortality
Bleaching observations	Severe bleaching response followed by near-100% mortality. Low stress resistance. Species generally fast growing and opportunistic. *Acropora, Pocillopora*	Graduated bleaching response with pale tissue, moderate mortality and recovery. Moderate to high stress resistance. Species generally slow growing, some large.	Persistent bleaching, low mortality. Moderate to high stress resistance. *Porites, Turbinaria, Astreopora*.
Life history strategy	Competitive and opportunistic	Intermediate/variable	Stress/adversity resistance

is a function of growth rates, where rapid growth is only possible for high surface area:volume growth forms such as branches and thin plates, and reproductive output is a direct function of capacity for photosynthetic output, egg production and tissue area. Branching corals are clearly the most susceptible to severe bleaching and to mortality following bleaching (Table 3) (Loya et al. 2001, Obura 2001, McClanahan 2004), while slow growing massives of both small and large sizes are the most stress resistant species (Table 1). Other variables such as tissue thickness are less clear in this regard, and further research may reveal a link.

In building up evidence for or against this hypothesis, the considerable variability in bleaching responses, and in the first-order responses that may dramatically alter the induction and appearance of bleaching, must be carefully considered. For example, a straightforward interpretation would state that stress tolerant corals would bleach earlier but more mildly than fast growing corals (Figs. 2 & 3). This can be seen in some cases of seasonal bleaching where small and large *Porites* massive colonies in lagoon reefs in East Africa often bleach at temperatures in the local spring (rapidly rising but intermediate temperatures in November) that don't cause bleaching in more susceptible species (pers. obs.). But during local-summer bleaching the first corals to bleach are usually the competitive and opportunistic genera. As expected though, they do tend to bleach more severely (steep response curve) and suffer mortality early. It may be that many of the pre-bleaching stress responses (Obura 2009) in stress tolerant corals are also tuned to an adversity response such that they effectively minimize internal stress thus pushing the bleaching induction threshold farther up the stress gradient than suggested by Figs. 2b and 3 with a combined effect of raising the maximum bleaching threshold.

The complex interactions and multiple stress responses in coral-zooxanthellae symbiosis (Brown 1997) contribute to variability in observed responses and explanations of bleaching (Coles and Brown 2003, Hoegh-Guldberg 2005) and a broad phase-space of bleaching-mortality dynamics (McClanahan 2004). As noted by Douglas (2003) this argues against overly-deterministic attempts to explain bleaching in terms of single phenomena. This life history model based on whole-organism emergent behaviour (Obura 2009) helps to identify patterns of acclimatization and adaptation above the detail of individual mechanisms that are precursors to the bleaching response itself.\

Abstract. Understanding how corals and coral-dependant organisms respond to major disturbances is critical in predicting long-term changes in the structure and dynamics of coral reef assemblages affected by ongoing climate change. This study documents changes in coral and butterflyfish assemblages at Trunk Reef in the central Great Barrier Reef, Australia, following severe climate-induced coral bleaching in 2001-02. Coral cover declined by 90%, to a low of 3.2% (± 0.8SE) in March 2005. However, coral cover has started to recover, increasing to 6.5% in January 2008 (±1.0 SE). Despite recent increases in the abundance of corals there has been no apparent increase in abundance of butterflyfishes. If anything, overall densities of butterflyfishes declined even further between 2005 and 2008, due to recent declines in the abundance of non-coral feeding butterfly fish. Although there are some signs of coral recovery, it is clear that severe episodes of coral bleaching can have enduring effects on coral reef ecosystems, and that recovery typically takes many years (>5 years). Protracted declines and limited recovery of coral and fish communities indicate that reef ecosystems will gradually deteriorate as bleaching events become more frequent and more severe.

Key words: Bleaching, Butterflyfishes, Coral Reefs, Coral loss, Disturbance, Reef fishes

Introduction

Coral reef ecosystems are subject to frequent and often catastrophic disturbances caused by a variety of different agents, including severe tropical storms, freshwater plumes, temperature extremes, and infestations of the coral eating crown-of-thorns sea star. These acute, but increasingly frequent, disturbances often cause marked reductions in the abundance of reef-building corals (Hughes et al. 2003; Hoegh-Guldberg et al. 2007), which are the major architects and significant contributors to endogenous carbon production on coral reefs. Changes in the physical and biological structure of benthic reef habitats are likely to have further, often detrimental, effects on other reef associated organisms, particularly coral reef fishes (Wilson et al, 2006; Pratchett et al. 2008a).

Among those fishes with the greatest reliance on hard corals are butterflyfishes from the genus Chaetodon (family Chaetodontidae), many of which feed on hard corals (Harmelin-Vivien and Bouchon-Navaro 1983; Halford et al. 2004; Pratchett 2005). Spatial variation in the abundance of butterflyfishes is often strongly correlated with hard coral cover (Cadoret et al. 1999; Pratchett and Berumen 2008), indicating a close association between butterflyfishes and coral prey. Moreover, many butterflyfishes exhibit rapid and dramatic declines in abundance following coral depletion (Williams 1986; Pratchett et al. 2006; Graham 2007).

The strong reliance on corals by coral-feeding butterflyfishes makes them very susceptible to effects of climate-induced coral bleaching (Pratchett et al, 2006). However, provided bleaching is sporadic and does not cause 100% mortality of critical coral species, even highly susceptible fish populations may have the potential to persist and recover. The recovery and resilience of fishes will however, be critically dependant upon recovery of coral habitats (Halford et al. 2004). In the absence of any further disturbances, it may take as little as 5 years for coral cover to return to pre-disturbance levels (Halford et al. 2004), though this will depend on the severity and spatial extent of coral loss, which dictates the ability of surviving corals to recover, reproduce and reseed affected areas (Hughes and Connell 1999; Riegl and Piller 2003; Golbuu et al. 2007). Recovery will be much faster if at least some coral colonies survive the bleaching (Baird and Marshall 2002), because growth of surviving corals leads to more rapid increases in coral cover compared with settlement and subsequent growth of new individuals (Connell et al. 1997).

The purpose of this study was measure rates of recovery in butterflyfish and coral assemblages at Trunk reef, Great Barrier Reef (GBR), Australia, following climate-induced coral bleaching in 2001-

02. Coral depletion was further exacerbated by localised outbreaks of *Acanthaster planci* causing extensive and widespread coral loss throughout the region (Sweatman et al. 2004). Periodic monitoring of butterflyfish and coral assemblages have been undertaken at Trunk Reef since May 2000, testing for long-term changes in abundance of both fish and corals. Until 2005, both coral cover and abundance of most butterflyfishes had exhibited significant declines (Pratchett et al. 2006). It was expected however, that coral cover would have increased significantly from 2005 to 2008, and that coral recovery would initiate commensurate increases in the abundance of coral-dependant butterflyfishes, following Halford et al. (2004).

Material and Methods

This study was conducted at Trunk Reef (18°17'S, 146°53'E), in the central section of the Great Barrier Reef (GBR), Australia. Trunk reef is a large (ca. 125km^2) submerged reef, located ~120km north of Townsville. This reef, like many throughout the GBR, was subject to extensive and wide-spread coral bleaching during the summer (November – March) of 2001-02 (Berkelmans et al. 2004). In order to assess impacts of coral bleaching, local assemblages of both scleractinian corals and butterflyfishes were examined at Trunk Reef in May 2000 (18 months before the bleaching), in March 2002 (towards the end of the bleaching event), in March 2005 (3 years after the bleaching), and most recently, in January 2008 (>5 years post-bleaching). Sampling was conducted on the shallow reef crest (2-3m water depth), at three randomly selected sites along the exposed (south-east) side of Trunk Reef. All sites were non-overlapping and independent, but were very similar in their physical structure, aspect, and exposure to prevailing south-east trade winds.

In 2000, 2002, and 2005, coral cover and composition were assessed using replicate 10-m line-intercept transects. Ten replicate transects were sampled at each site. On each transect, colonies lying directly beneath the transect tape were identified to genus and the intercept length measured to the nearest centimeter. Percentage cover for each taxa was then calculated based on the cumulative intercept length of each taxa on each transect. In 2008 however, coral cover and composition was quantified using photographic records of the benthos taken at 1-m intervals along the length of 50-m transects that were deployed to survey butterflyfishes. Within each photograph we recorded the substrate type or benthic organisms immediately beneath the transect line corresponding with 1-m markings (e.g., 1.0, 2.0 etc).

Densities of butterflyfishes on the reef crest at Trunk reef were quantified using underwater visual census (UVC) along 50-m transects. Adult butterflyfishes observed within 2-m either side of the transect line were counted and recorded to species. All transects were positioned within 10-m of the edge of the reef crest, following the natural contours of the reef. Five replicate transects were conducted at each site. To test for differences in responses of butterflyfishes according to their specific trophic requirements (following Pratchett et al. 2006; Graham 2007), all species were categorised as either i) obligate corallivores (OC), ii) facultative corallivores (FC), or iii) non-coral feeders (NC). Species were assigned to feeding guilds following Pratchett (2005).

Results

Coral cover on the reef crest at Trunk reef declined significantly between May 2000 and March 2005, to a low of 3.2% (± 0.8SE) in March 2005 (Fig. 1, Table 1). Since 2005, there has been a 100% increase in coral cover to 6.5% (±1.0 SE) in January 2008 (Fig. 1). Recent increases in coral cover are mainly due to increased cover of *Acropora* species (Table 1), especially *A. hyacinthus*. In January 2008, mean cover of *Acropora* spp. was 4.8%, accounting for 73% of live coral cover, compared to 14% and 4%, for the next most abundant genera, *Pocillopora* and *Porites*, respectively. Other genera (comprising mainly *Favites*, *Goniastrea*, *Montipora*, and *Stylophora*) together accounted for only 8% of coral recorded in 2008.

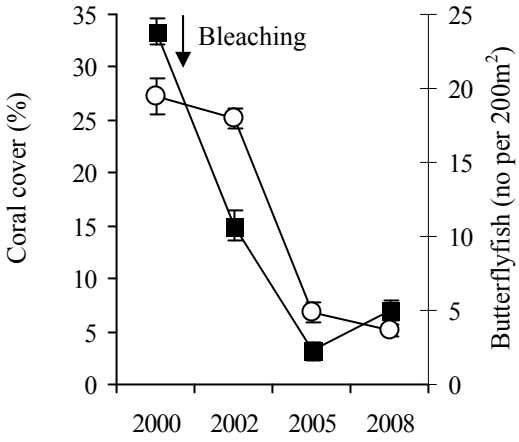

Figure 1. Mean ± SE percentage cover of scleractinian corals (■) and densities of butterflyfishes (O) at Trunk Reef in May 2000 (before bleaching), March 2002 (during bleaching), March 2005, and January 2008 (post-bleaching).

Table 1. Changes (%) in coral cover and butterflyfish abundance at Trunk Reef over two distinct intervals (2000-2005, and 2005-2008) Absolute changes were analysed using nested ANOVAs (between years and among sites within years), with F and p shown for temporal contrasts. Coral cover data was arcsine- square root transformed, while butterflyfish densities were $\log_{10}$ transformed prior to analyses (df = 1, 4). Values in bold are significant even when applying Bonferroni correction for multiple comparisons across coral genera and trophic groups for butterflyfishes (OC – Obligate corallivores, FC – Facultative corallivores, and NC – Non-coral feeders).

	2000-2005		2005-2008

Despite recent increases in coral cover at Trunk Reef, there has not been any concomitant increase in the abundance of butterflyfishes (Fig. 1). Mean densities of butterflyfishes declined from 19.5 (±1.2SE) fishes per 200m^2 (per transect) in March 2000 down to 3.7 (±0.4SE) fishes per 200m^2 in January 2008. The greatest decline occurred between 2002 and 2005, but there have been further (albeit not significant) declines between 2005 and 2008 (Fig. 1).

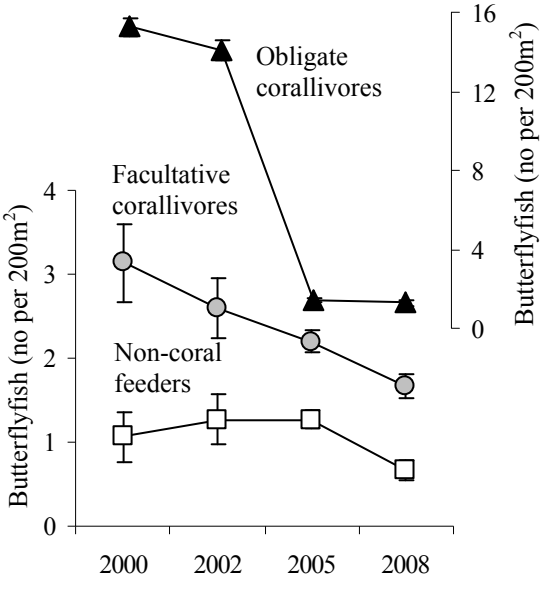

Figure 2. Temporal variation in mean ± SE densities of butterflyfishes within each trophic group (i. obligate corallivores, ii. facultative corallivores, and iii. non-coral feeders) on the reef crest at Trunk Reef

The group of butterflyfishes that exhibited the most rapid and dramatic declines in abundance following extensive coral depletion were the obligate coral feeders (comprising *Chaetodon aureofasciatus, C. baronessa, C. lunulatus, C. plebeius, C. rainfordi,* and *C. trifascialis*). Between 2002 and 2005, the proportional decline in abundance of these species corresponded very closely to the decline in total coral cover (Table 1). Densities of obligate corallivores have remained at or below 1.4 (±0.8SE) fishes per 200m^2 since 2005 with no evidence of recovery (Table 1).

Facultative corallivores (e.g., *C. citrinellus* and *C. melannotus*) and non-coral feeding butterflyfishes (e.g,, *C. auriga* and *C. vagabundus*) did not exhibit any significant variation in abundance to 2005 (Table 1), though there was an apparent downward trend in mean densities of facultative corallivores throughout this study (Fig. 2). For non-coral feeders, there was no apparent change in abundance between 2000 and 2005, but there have been significant recent declines in abundance (Table 1), from 1.3 (±0.1SE) fishes per transect in 2005 down to 0.7 (±0.1SE) in 2008 (Fig. 2).

Discussion

Climate-induced coral bleaching represents one of the most significant and increasingly prevalent disturbances to coral reef ecosystems, which not only causes extensive coral mortality, but also reduces the abundance of many other coral reef organisms that are reliant on corals for food, shelter or recruitment (Wilson et al, 2006; Pratchett et al, 2008a). At Trunk Reef, extensive coral depletion was accompanied by a 5-fold reduction in the abundance of butterflyfishes. Declines in abundance of butterflyfishes were most rapid and most severe for obligate corallivores, which is to be expected given their obligate dependence on coral for food. Corallivorous fishes have the most apparent and direct reliance on live corals and are consistently among the worst affected fishes following extensive coral loss (Wilson et al. 2006).

The extent to which corallivorous fishes feed on corals (versus other non-coral prey) is highly variable (e.g., Hobson, 1974; Pratchett, 2005) and obligate coral-feeders are much more affected by coral loss than facultative coral-feeders (Bouchon-Navaro et al. 1985; Williams 1986; Pratchett et al. 2006; Graham 2007). Accordingly, facultative corallivores were relatively unaffected by initial declines in abundance of corals at Trunk Reef. These fishes presumably persisted on increased intake of non-coral prey, but there has been a persistent decline in abundance of these fishes throughout the study, suggesting that corals may represent an important and necessary component of their diet. Alternatively, protracted

declines in the abundance of these fishes may be attributable to the loss of habitat structure or habitat diversity associated with extensive coral loss (Graham et al. 2006; Pratchett et al. 2008a), and this may also be the reason why non-coral feeding butterflyfishes have ultimately declined in abundance >5 years after the initial coral loss. It is also possible that coral depletion has reduced settlement success by butterflyfishes (Jones et al. 2004), which might explain protracted declines in population size. However, butterflyfishes with low coral content in their diet as adults tend not to recruit to live corals (Pratchett et al. 2008b), but overall declines in habitat complexity may have reduced post-settlement survivorship of all species (Graham et al. 2007).

Topographic complexity of coral reef habitats has an important influence on biotic interactions, such as predation and competition, and has a major influence on the local abundance of coral-reef fishes, especially during early life stages (Almany 2004; Hixon and Jones 2005). Climate-induced coral bleaching kills corals, but leaves the underlying skeleton completely intact (Hoegh-Guldberg 1999). Exposed coral skeletons are then subject to a whole suite of bio-eroding organisms that undermine the structural integrity of these carbonate structures (Hutchings 1986). Reef habitats with reduced topographic complexity typically support lower fish abundance, fewer species, and increased evenness (Gratwicke and Speight 2005; Graham et al. 2006).

This study focused on specific study locations along the exposed reef crest at Trunk reef as baseline data on coral and butterflyfish assemblages were recorded prior to the bleaching in 2000 (Pratchett et al. 2004, 2006). However, the extent of coral depletion and declines in abundance of butterflyfishes (especially corallivorous species) reported for Trunk Reef are similar across the full range of locations (reef crest and reef slope habitat at three different reefs; Trunk Reef, Bramble Reef and Rib Reef) surveyed since 2002. Interestingly however, coral recovery has been highly variable within and among reefs. At Bramble reef, for example, there are two sites where coral cover has increased to 90% within the 5 years since the bleaching (Fig. 3). Even so, there has been no apparent recovery of butterflyfishes at any of these sites. These findings contradict previous studies that suggested recovery of fishes would closely follow coral recovery (Halford et al. 2004). Recovery of fish populations at these sites appears to be currently limited by a lack of new recruits. Recruitment rates by butterflyfishes are generally low (Pratchett et al. 2008b) and may have been further constrained by limited coral cover at potential settlement sites, as well as widespread depression of breeding populations.

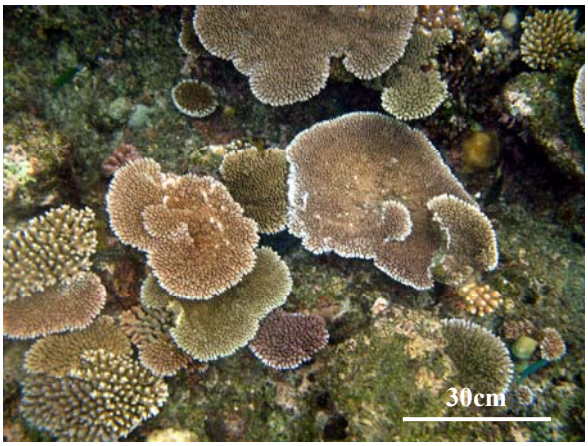

Figure 3. Extensive cover of *Acropora* (mostly, *A. hyacinthus*) at Bramble Reef in January 2008.

The rapid recovery and increasing dominance of *Acropora* spp. in the aftermath of extensive coral bleaching suggests that climate forcing of coral communities may initially favor coral species with rapid recovery potential, rather than slow-growing corals that might otherwise have greater resistance to bleaching, as suggested previously (Hughes et al. 2003; McClanahan et al, 2007). Fortunately, faster growing corals (especially *Acropora*) contribute most to topographic complexity of reef habitats (Sheppard et al. 2002) and are also the major corals used by corallivorous and coral-dwelling fishes (Munday et al. 1997; Pratchett 2005). However, persistence of *Acropora* populations will depend on sufficient time between successive bleaching events to allow for recovery. Recovery was mostly very limited (but occasionally spectacular) in the 5 years since extensive bleaching in the central GBR. Donner et al. (2005) project that bleaching is likely to occur at least every 2 years on most coral reefs around the world by 2040, meaning that there would be insufficient time for recovery of *Acropora* spp., let alone other slower growing species (e.g., *Porites*). Sustained and ongoing climate change will undoubtedly change the community structure of coral assemblages (Hughes et al. 2003; McClanahan et al. 2007), yet specific effects will depend on the severity, extent and recurrence of future bleaching events.

In conclusion, this study shows that coral communities are starting to recover at Trunk Reef. However, recovery has been very slow and follows highly protracted declines in coral cover. Moreover, coral depletion led to extensive and long-term declines in the abundance of butterflyfishes, and these fishes are yet to respond to increased availability of corals, which are critical in providing both food and habitat (Pratchett et al. 2006). These systems are likely to recover in the absence of any further

disturbances. However, it is clear that projected increases in the frequency and severity of coral-bleaching events are likely to cause extensive ongoing degradation and biodiversity loss on coral reefs throughout the world (Hoegh-Guldberg et al. 2007).

Coral ultrastructural response to elevated pCO_2 and nutrients during tissue repair and regeneration

D.A. Renegar[1], P.L. Blackwelder[1,2], A.L. Moulding[1]

1) National Coral Reef Institute, Nova Southeastern University Oceanographic Center, 8000 North Ocean Drive, Dania, FL 33004
2) University of Miami RSMAS, 4600 Rickenbacker Causeway, Miami, FL 33149

Abstract. Corals and coral reefs have recently experienced widespread decline attributed to anthropogenic pressure on reef systems. Studies have demonstrated that nutrient and pCO_2 stress effect coral growth and calcification, but study of specific effects on coral tissue is lacking. The objective of this research was to examine wound healing in corals and how it is affected by exposure to elevated nutrients and pCO_2. Coral tissue repair and regeneration during wound healing in *Montastraea cavernosa* and *Porites astreoides* were assessed histologically and ultrastructurally by examining colony fragments exposed to elevated nitrate, phosphate, and pCO_2. In *M. cavernosa*, tissue repair was facilitated by granular amoebocytes, and the zooxanthellae population size increased under enriched nutrient conditions. In *P. astreoides,* zooxanthellae chloroplasts were markedly abnormal in phosphate-enriched corals, and the concentration of chromophore cells at the healing tissue front was markedly lower under elevated nutrient conditions. The area of wound healed was higher after 14 days under every experimental condition in *M. cavernosa* compared to *P. astreoides*. In both species, phosphate enrichment had the most deleterious effect on repair and regeneration.

Key words: coral ultrastructure, tissue repair, pCO_2, nutrient enrichment.

Introduction

A growing global population and the close proximity of coral reefs to coastal areas has resulted in increasing anthropogenic pressure on reef systems. In recent history, the implications of environmental change on coral reefs have become progressively more far-reaching. Both nutrification and global climate change (including increasing atmospheric pCO_2 and temperature) are sources of nonspecific general anthropogenic stress to corals. Other sources, such as over-fishing, sedimentation and turbidity from dredging and beach restoration activities, have deleterious effects on corals (Szmant 2002, Vargas-Ángel et al. 2005). In addition, direct physical damage can result from storms, coral collection, dynamite fishing, blasting, and ship groundings (Curtis 1985, Szmant 2002). Physical damage events, coupled with existing eutrophication stress (a complex process of organic production and accumulation) and changing global climate present a poor outlook for successful natural recovery of reef communities and individual colonies (Szmant 2002).

Elevated nutrient and pCO_2 levels in areas prone to physical damage may contribute to a reduced ability of damaged corals to successfully heal and survive. Significant decreases in calcification rate and/or growth rate have been observed in several species at nitrate concentrations of <5 μM (Tomascik and Sander 1985, Bell and Tomascik 1993, Marubini and Davies 1996, Renegar and Riegl 2005) and at phosphorus concentrations of >1 μM (Kinsey and Davies 1979, Walker and Ormond 1982, Tomascik and Sander 1985, Ferrier-Pagès et al. 2000, Renegar and Riegl 2005). Increasing atmospheric CO_2 partial pressure (pCO_2) is predicted to alter ocean surface carbonate saturation, resulting in reduced reef growth (Leclercq et al. 2000, Guinotte et al. 2003, Hughes et al. 2003). The possible effects of low pH and CO_3^{2-} (including weaker skeletons and increased erosion) may have a greater impact on net calcification than nutrient enrichment (Kleypas et al. 1999, Marubini and Atkinson 1999).

The process by which tissue repair takes place and normal function restored is a complex process that has been described in other calcifying aquatic organisms but remains largely uninvestigated in scleractinians. The mechanism of invertebrate tissue repair, organic matrix production and skeletal deposition has been ultrastructurally studied, for example, in echinoderms and molluscs (Wilbur 1973, Meenakshi et al. 1975, Blackwelder and Watabe 1977). Mollusc epithelial ultrastructure changes dramatically during repair, and the minerals formed differ from normal morphology and mineralogy (Watabe and Blackwelder 1980). In corals, most studies have focused on physical parameters such as lesion or colony size. Lesional

perimeter length is likely the most important factor in regeneration, although the size, shape and location of lesions can be significant (Meesters et al. 1997, Oren et al. 1998, Lirman 2000). Regeneration may be supported by a limited amount of energy related to the extent of damage, an aspect possibly linked to colony size (Bak and Van Es 1980, Lirman 2000).

A more complete understanding of the effects of anthropogenic environmental factors on coral cell biology is essential to reef management and prediction of the capacity for natural recovery. This goal of this study was to examine the process of tissue repair in corals and how it is affected by elevated nutrients and pCO_2. The target species, *Montastraea cavernosa* and *Porites astreoides*, are important and widespread Caribbean reef corals.

Materials and Methods

Four colonies each of *M. cavernosa* and *P. astreoides* were acclimated to laboratory conditions. Colonies were cut into 4 cm^2 fragments. A wound (~4 mm wide and 2 cm in length) was created with a rotary tool in each fragment, and fragments were placed in experimental tanks. Experiments were conducted in 20 separate (8 l) flow-through aquaria partially submerged in a water bath to control temperature variation between tanks. Five treatment conditions were maintained, with two tanks and 32 fragments of each species for each treatment: control; nitrate enrichment; phosphate enrichment; nitrate and phosphate, and pCO_2 enrichment. Each set of treatment tanks was continuously supplied with natural seawater from reservoirs dosed at a specific rate. Irradiance was supplied by metal halide lamps (175 watt, 10,000K, photoperiod 12:12).

Elevated mean nutrient concentrations of 10.8 (±0.5) µM NO_3^- and 4.4 (±0.3) µM $P\text{-}PO_4^{3-}$ were achieved by addition of KNO_3 and KH_2PO_4 to reservoirs supplying the appropriate tanks. Nitrate concentration was determined with NECi Saltwater Nitrate Test Kit (SW-NTK). Phosphate concentration was determined utilizing the method of Parsons et al. (1984). Elevated mean pCO_2 concentrations of 1381 (±66) µatm were achieved with a pH controlled CO_2 injected reservoir system described by Reynaud et al (2003). Total alkalinity and pH were used to monitor pCO_2.

Corals were maintained under experimental conditions for 14 days. Fragments were then fixed in glutaraldehyde fixative solution [2 mL 70% glutaraldehyde in 68 mL cacodylic buffer (2.16 g cacodylic acid in 200 mL of .22 µm filtered seawater)]. Samples were maintained at 4°C in the fixative solution for 1-2 days, rinsed in buffer, and subsequently post-fixed in buffered 1% osmium tetroxide solution (5 mL 4% aqueous osmium tetroxide in 30 mL of cacodylic buffer) for 1 hour. Samples were again rinsed in buffer and then dehydrated in a graded series of ethanols. Excess skeleton was trimmed and the samples were embedded in Spurr resin. Ultrathin sections were cut (40 to 60 nm thick) using a Sorval MT-2 ultramicrotome fitted with a diamond knife. Sections were retrieved on nitrocellulose and carbon coated 200 mesh copper grids, stained with Reynolds lead citrate and/or 2% uranyl acetate solution, and viewed in a Phillips 300 TEM.

After fixation and dehydration as discussed above, SEM samples were dried in HMDS, mounted on carbon adhesive covered aluminum stubs, coated with palladium in a sputter coater and examined in an FEI XL-3- ESEM fitted with an Oxford EDS for elemental analysis of the calcified structures.

Histological samples were decalcified after primary fixation in 5% HCl/EDTA solution, dehydrated and embedded in Paraplast®, sectioned and stained with Hematoxylin & Eosin.

Results

Wound healing and closure was affected by nutrient and CO_2 enrichment. Area analysis of percent wound healing for each treatment was performed using Coral Point Count (Kohler and Gill 2006) (Table 1). In *M. cavernosa*, 15% of the wounded corals for all treatments fully healed after 14 days. In *P. astreoides*, none of the wounded corals fully healed. In both species, phosphate enrichment had the greatest deleterious effect on the percent of wound repaired. The effect of pCO_2 was similar to that of nitrate enrichment alone.

Table 1. CPCe (V 3.5). Mean percent wound healing in each treatment for *Montastraea cavernosa* and *Porites astreoides*.

	Montastraea cavernosa	***Porites astreoides***
Control	**87% ± 11%**	**24% ± 5%**
Nitrate/Phosphate	**85% ± 17%**	**9% ± 13%**
Nitrate	**79% ± 11%**	**10% ± 16%**
Phosphate	**58% ± 26%**	**2% ± 6%**
pCO_2	**75% ± 20%**	**10% ± 11%**

Montastraea cavernosa. Histological analysis indicated that tissue repair in *M. cavernosa* was characterized by rapid granulation of tissue across the wound site, facilitated by granular amoebocytes. These amoebocytes coalesced to form new tissue at the healing front (arrows) (Figs. 1A & 1C). No histological differences in the coral tissue have thus far been observed between the treatments. However, the zooxanthellae population number appeared to increase in response to nutrient enrichment (Figs. 1B & 1D).

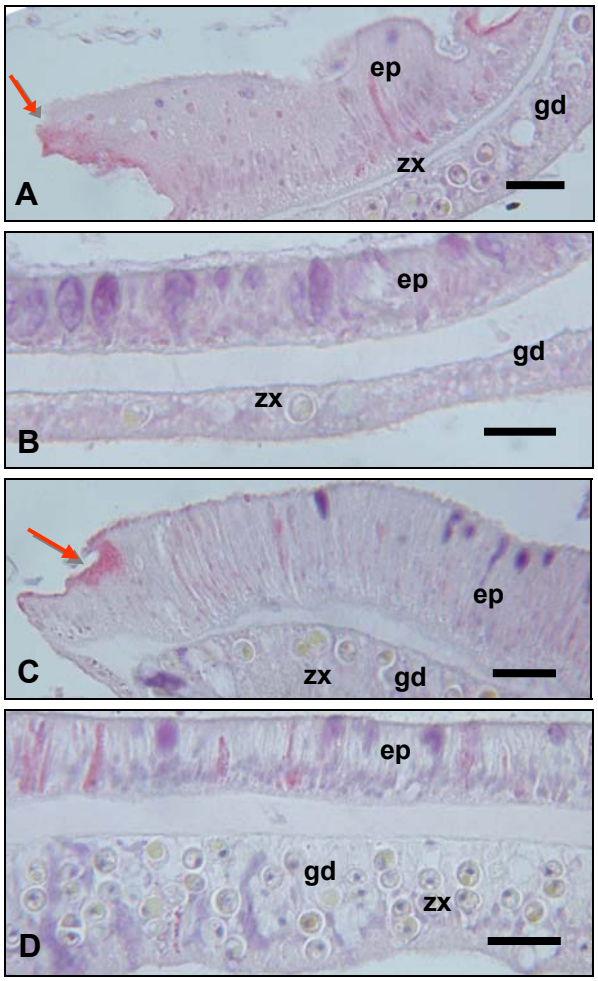

Figure 1. *Montastraea cavernosa*. Histological micrographs. A) Control, B) CO_2 enriched, C) nitrate & phosphate enriched and D) phosphate enriched. ep: epidermis; gd: gastrodermis; zx: zooxanthellae. Scale bars: A, B, C & D = 20 µm.

Ultrastructural observations revealed that granular amoebocytes were migrating to and integrating with new tissue at the repairing interface (Figs. 2A & 2B). Newly formed tissue was dense with well-defined cell walls and a distinct granular appearance (Fig. 2C). Zooxanthellae appeared healthy and were in various stages of cell division. Preliminary data indicates few distinct differences in tissue ultrastructure between nutrient, CO_2, or control treatments.

Porites astreoides. Tissue repair in *P. astreoides* was characterized by an increased concentration of chromophores near the healing tissue front (arrows). This was pronounced in control and CO_2 treatments (Figs. 3A & 3B). In contrast, the nutrient enriched corals appeared to exhibit fewer chromophores near the repairing front (Figs. 3C & 3D), and the gastrodermis was thickened. Vacuolization was observed in phosphate treated tissue, suggesting zooxanthellae degradation (Fig. 3D).

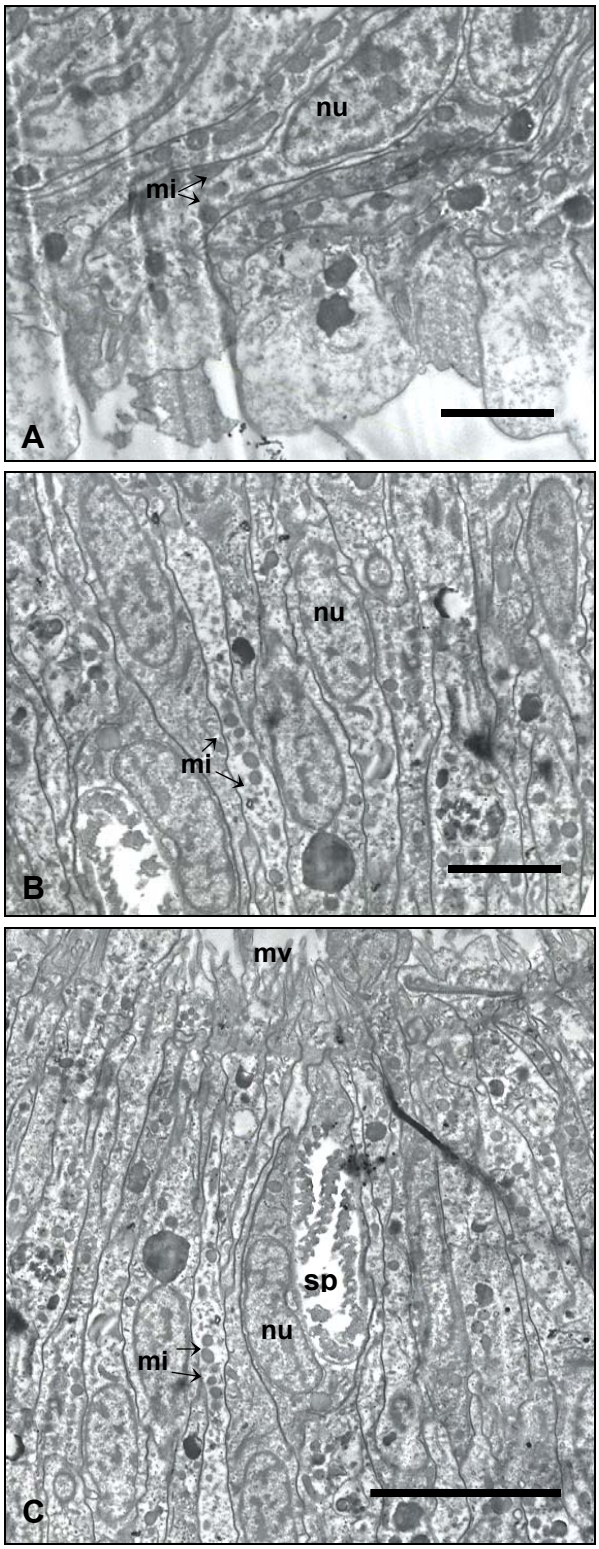

Figure 2. *Montastraea cavernosa*. TEM micrographs. A) Coalescent granular amoebocytes, B) mid-stage tissue formation, and C) late-stage tissue formation. mi: mitochondria; mv: microvilli; nu: nucleus; sp: spirocyst. Scale bars: A = 4 µm, B & C = 5 µm.

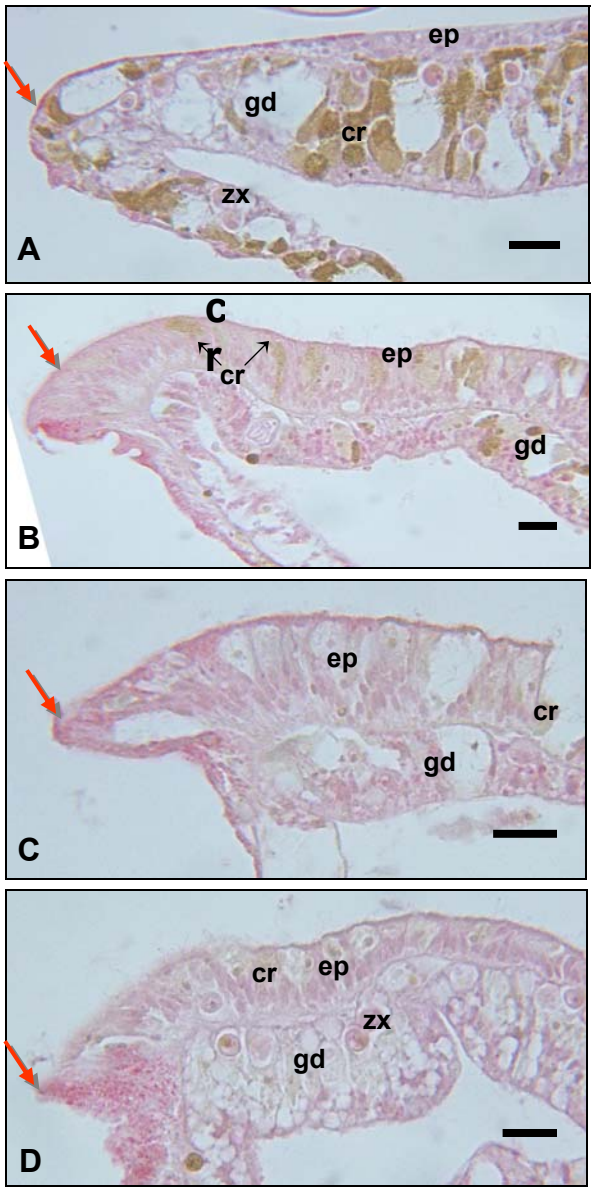

Figure 3. *Porites astreoides.* Histological micrographs. A) Control, B) CO_2 enriched, C) nitrate & phosphate enriched and D) phosphate enriched. cr: chromophore; ep: epidermis; gd: gastrodermis; zx: zooxanthellae. Scale bars: A, B, C & D = 20 µm.

Fine-structural examination (SEM) of the repairing tissue confirmed the presence of chromophores accumulating at the healing tissue front (oval) (Fig. 4A). Ultrastructural examination revealed mature granules within the chromophore cells (Fig. 4B). Abnormal zooxanthellae were observed in the phosphate-enriched corals, with significantly degraded chloroplast lamellae and cellular wall disruption (Fig. 4C). These effects are currently being assessed in greater detail.

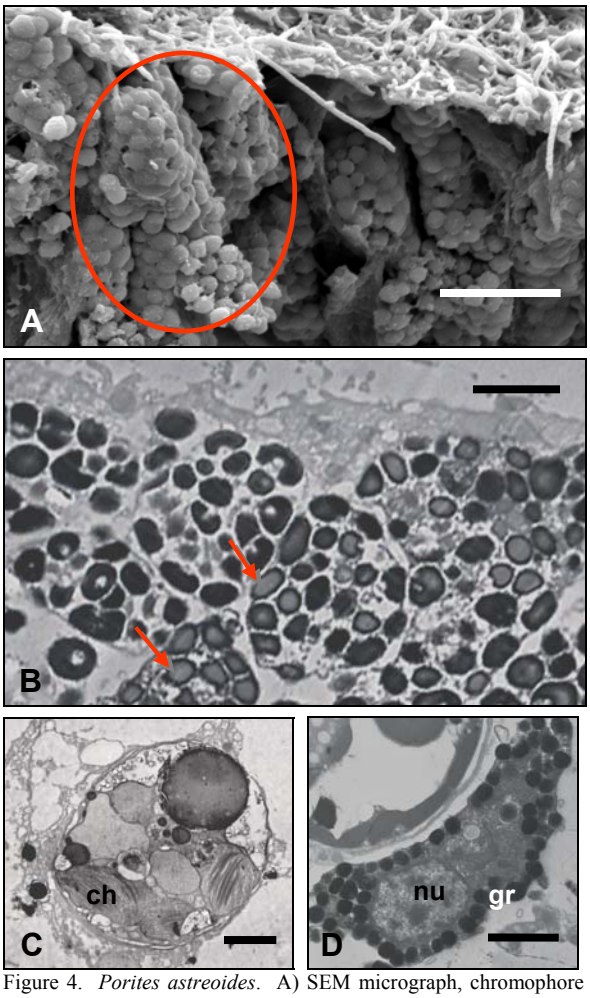

Figure 4. *Porites astreoides.* A) SEM micrograph, chromophore cell accumulation in healing tissue. TEM micrographs, B) mature granules in chromophores, C) phosphate-enriched zooxanthellae and D) mast-type cell in early stage tissue repair. ch: chloroplast; gr: granule; nu: nucleus. Scale bars: A = 5 µm, B, C & D = 2 µm.

Discussion

Tissue repair in *M. cavernosa* was characterized by granulation of new tissue across the wound site, facilitated by coalescent granular amoebocytes. This is similar to observations in gorgonians (Meszaros and Bigger 1999). As little organic matrix was observed associated with the calicodermis near the repairing front, the wound healing strategy of this species appears to emphasize rapid wound closure and formation of new tissue before calcification resumes. The percentage of wound repair was highest in the controls, and lowest in the phosphate treatment. Zooxanthellae concentration appeared higher near the healing front in the nutrient treatments compared to the control or CO_2 treatments. The variation in zooxanthellae concentration is likely due to the interaction between regeneration energy demands and the presence of limiting nutrients, as overall increases in zooxanthellae concentrations have been found in

wounded gorgonians compared to non-wounded (Meszaros and Bigger 1999). This aspect is currently being studied in greater detail.

In contrast to *M. cavernosa*, the wound repair strategy of *P. astreoides* appeared to involve rapid sealing and reorganization of the tissue and continuation of calcification, with closure achieved by recalcification across the wound. This is supported by the marked effect of nutrients and pCO_2 on wound closure rate in this species. Accumulation of chromophores at the healing tissue front was notable in the control and CO_2 treatments, in contrast to the few seen adjacent to the tissue front in the nutrient treatments. Interestingly, the ultrastructure of some chromophores was similar to vertebrate mast cells (Fig. 4D) (Porter and Bonneville 1974). Chromopphores may have many functions, including involvement in tissue repair and the coral immune response. For example, differences in chromophore ultrastructure have been observed in healthy vs. diseased *P. astreoides* (Kacszmarsky, pers. com.).

The synergistic effect of nitrate and phosphate combined appeared to be antagonistic in both species. Similar observations have been made regarding growth rate and calcification in other coral species. The effect of nitrate and phosphate combined on the growth rate of *Acropora cervicornis* was additive at low concentrations (5 μM NO_3^- and 2 μM P-PO_4), and antagonistic at high concentrations (10 μM NO_3^- and 4 μM P-PO_4) (Renegar and Riegl 2005). This effect may be a consequence of disruption of the coral-zooxanthellae relationship resulting from the stress of and energy requirements for regeneration and repair (Meszaros and Bigger 1999).

Abstract. Global climate change and direct anthropogenic stress factors lead to gradual replacement of hermatypic corals by benthic algae at many reef locations, a process which is commonly referred to as phase shift. Recent research showed that corals via the release of organic matter and concomitant effects on cycles of matter can act as engineers of reef ecosystems. There are strong indications that reef associated benthic algae do also affect reef ecosystem functioning via organic matter release, but relevant information is lacking. To gain a better understanding of the biogeochemical consequences such phase shifts may entail, a series of comparative studies with corals and algae was conducted in reefs of the Northern Red Sea during four seasonal expeditions in 2006-2008. These investigations focused on the quantity and quality of the organic matter released by both groups of organisms involving dissolved organic carbon (DOC), particulate organic carbon (POC) and nitrogen (PN) along with the respective stable isotope signatures. Planktonic and benthic degradation of the released material were investigated using bottle incubation experiments and in-situ stirred benthic chambers. First outcomes show clear differences between organic matter release by corals and algae, thus suggest effects of phase shifts onto reef biogeochemical cycles.

Key words: corals, reef algae, organic matter release, phase shift, community metabolism

Introduction

It is generally assumed, that the global climate change along with direct anthropogenic factors like eutrophication and overfishing lead to phase shifts in coral reefs, i.e. the gradual replacement of reef building corals by benthic algae (Hoegh-Guldberg 1999, Hughes et al. 2003, Pandolfi et al. 2005, Hoegh-Guldberg et al. 2007, Hughes et al. 2007). Recent studies also showed that hermatypic corals can act as engineers of the entire reef ecosystem, particularly by the release of organic matter and associated effects on biogeochemical key processes and element cycles (Wild et al. 2004a, Wild et al. 2005b, Wild et al. 2008). This is a newly discovered aspect of corals as ecosystem engineers besides their long known ability to generate structural frameworks.

Moreover, the work of Smith et al. (2006) indicates that benthic reef algae can also affect processes such as microbial activity in their surroundings via a hypothetical release of organic matter. Reef algae may therefore act as (new) reef ecosystem engineers, but likely in a very different way. This pilot study presents first data based on comparative investigations with the dominant corals and benthic reef algae from four expeditions to the Northern Red Sea comprising the following three interrelated approaches: 1) Quantification of dissolved and particulate organic matter (DOM and POM) release, 2) Determination of POM stable isotope signatures, 3) Planktonic and benthic degradation of released exudates. These data will provide first comparative information on the quantity and quality of benthic algae-derived organic matter and its subsequent degradation in the different compartments of the ecosystem coral reef.

Material and Methods

The work for this study was conducted during four seasonal expeditions (Nov/Dec 2006, Aug/Sep 2007, Feb/Mar 2008, May 2008) to Marine Science Station (MSS), Aqaba, Jordan. Collection of all specimens took place in the MSS fringing reef in water depths of 5 to 7 m. During each of the field trips, 5 replicate fragments (coral branch length: 6 to 10 cm) were broken off in-situ from colonies of the dominant hard corals of the genera *Acropora*, *Pocillopora* and *Stylophora*, which were allowed to heal in a flow-through aquarium for at least 7 d prior to the

subsequent experiments. In addition, 5 replicate small pieces (lengths: 6 to 14 cm) of the 3 most dominant types of benthic algae were collected in-situ: the green algae *Caulerpa* spec., the red algae *Peyssonnelia* spec., and typical filamentous turf algae consortia growing on dead coral skeletons. All algae were left in a flow-through aquarium for at least 12 h prior to the subsequent experiments for cleaning and healing purposes. For the organic matter release quantification the beaker incubation technique described by Herndl and Velimirov (1986) was used. Corals and benthic algae were separately transferred into acetone- and seawater-rinsed 1000 ml glass beakers filled with 800 to l000 ml of untreated seawater freshly pumped from the field. Identical beakers, only filled with seawater, served as controls. Beakers were kept in a flow-through aquarium during day at in-situ temperature of 21 to 29 °C (caused by seasonal differences) as monitored by *Onset HOBO* temperature loggers. Nylon gauze was clamped above the beakers to simulate light intensities very similar to those at 5 m water depth as verified by *Onset Pendant* light loggers. After 6 h incubation duration, corals and algae were removed from the beakers and sub-samples were taken from the incubation water for determination of the following parameters.

Dissolved Organic Carbon (DOC): Circa 10 ml of the incubation water were filtered through 0.2 µm sterile syringe filters (polyethersulfone membrane). The first 4 ml of the filtrate were discarded, but the following 6 ml were collected in pre-combusted brown glass bottles or ampoules, which were instantly frozen at -20 °C and kept frozen until analysis. DOC concentrations were determined by high temperature catalytic oxidation (HTCO) using a Rosemount Dohrmann DC-190 total organic carbon (TOC) analyser. After defrosting, each sample was treated by adding 100 µl of 20 % phosphoric acid and purging for 5 min in order to remove dissolved inorganic carbon. DOC concentration of each sample was measured five times. An outlier test was conducted and the DOC concentrations of the remaining samples were averaged. Potassium hydrogenphtalate was used as standard for calibrating the DC-190 TOC analyser.

Particulate Organic Carbon (POC) and Nitrogen (PN): Between 400 and 940 ml of the incubation water were filtered onto pre-combusted GF/F filters (Whatman, 25 mm diameter), which were dried for at least 48 h at 40 °C and kept dry until analysis. POC and PN concentration measurements and respective stable isotope analyses were performed with a Carlo Erba NC 2500 elemental analyzer, coupled with a THERMO/Finnigan Conflo II- interface to a THERMO/Finnigan MAT Delta plus isotope ratio mass spectrometer. Elemental concentrations were calculated from certified elemental standards (Atropine, Cyclohexanone-2,4-dinitrophenylhydrazone; Thermo Quest, Italy) and typically showed standard deviations < 3 %. Stable isotope ratios are given in the conventional delta notation ($\delta\ ^{13}C$, $\delta\ ^{15}N$) relative to Vienna PeeDee Belemnite (VPDB) standard (Craig 1957, Coplen 1995) and atmospheric nitrogen (Mariotti 1984), respectively. Standard deviations for repeated stable isotope measurements of lab standard (Peptone) were better than 0.15 ‰ for nitrogen and carbon, respectively. Respective surface areas of all coral fragments and algae pieces were measured as reference parameter using geometric approximations (all corals and turf algae growing on dead coral fragments, see Naumann et al. (2009) or the image analysis software *Image J* to analyze digital photographs of the predominantly 2-dimensionally growing macro algae *Caulerpa* spec. and *Peyssonnelia* spec..

Planktonic microbial degradation: Circa 140 ml of the incubation water from each beaker was used to fill two 60 ml gas-proof glass bottles. Oxygen concentration in one of the bottles was measured immediately and in the second bottle after incubation of the enclosed water for at least 16 h in the dark and at in-situ temperature using Winkler titration (Winkler 1888) or a *Hach HQ 10* optode. Microbial activity in the incubation water was determined by subtracting final from start oxygen concentration. Planktonic microbial degradation of the added TOC was calculated by using the respective POC + DOC amounts and the increase in O_2 consumption in the bottles relative to the controls assuming that 1 mol added organic material is oxidized by 1 mol O_2.

Benthic degradation: Degradation of algae and coral exudates was studied in-situ by addition of algae- and coral derived organic material to stirred benthic chambers identical to those described by Huettel and Gust (1992). These in-situ experiments were conducted at a reef site with carbonate sands (2.5 m water depth) described in (Wild et al. 2005a). The duration of the individual chamber experiments ranged between 5 to 8 h. Prior to each experiment, chambers were gently inserted into the loose calcareous sands to a depth of about 12 cm, thus including a water column of approximately 20 cm height and 5.7 l volume. At the beginning of the first experiment, 81 µmol coral- and 310 µmol algae-derived organic matters were added to two chambers each. In a second independent experiment, 91 µmol coral- and 186 µmol algae-derived organic matters were again added to two chambers each, but only one of these two replicate chambers was stirred (advection

chamber) , whereas the other one was left without stirring (diffusive chamber). All 8 chambers of both experiments were incubated for 8 h in the dark. Water samples were regularly (at least every 2 h) collected from all chambers through a sampling port using plastic syringes, whereby the water from the diffusive chambers was thoroughly mixed before sampling in order to avoid O_2 concentration gradients. Oxygen concentrations were measured in the chamber waters using Winkler titration and benthic TOC degradation of the added algae or coral exudates were calculated as described above.

Results

All investigated benthic reef algae released both DOM and POM in measurable quantities. Data from the first two seasonal expeditions showed that organic matter release by corals and benthic algae was very different. In particular, DOC fluxes were one order of magnitude higher during autumn 2006 compared to summer 2007 (Table 1). There was no correlation between organic matter release and water temperature. All investigated benthic reef algae during both seasons showed DOC release, whereas DOC release by the corals was highly variable (as indicated by the large error bars) with often negative values, i.e. DOC uptake (Table 1). POC release could be detected for all investigated specimens, but showed no seasonal differences with similar release rates in autumn and summer. However, corals generally released significantly more POC than algae (U-test after Wilcoxon, Mann and Whitney, $p < 0.05$). The C:N ratios and nitrogen stable isotope signatures of algae and coral-derived particulate organic matter (POM) were not significantly different, but carbon stable isotope signatures of algae-derived POM ($\delta\ ^{13}C$: -10.1 ± 1.4 ‰) were significantly more positive ($p < 0.05$) than those of coral-derived POM ($\delta\ ^{13}C$: -18.3 ± 0.3 ‰). POM C stable isotope signatures were very similar to that of sterile coral mucus ($\delta\ ^{13}C$: -18.2 ± 1.2 ‰; Naumann et al. unpublished data), thereby demonstrating the apparent dominance of this material in the coral beakers. The respirometric experiments from all 4 seasons revealed that microbial activity measured as O_2 consumption was only significantly higher in the algae incubation water compared to that of the corals in autumn, but not during the other three seasons. Resulting microbial Total Organic Carbon (TOC = POC + DOC) degradation rates in autumn were 0.57 ± 0.38 and 0.18 ± 0.02 % h^{-1} for the algae- and coral-derived exudates, respectively. Benthic degradation of both organic matter sources showed an opposite trend with twice as high TOC degradation rates for the added coral exudates (23.7 ± 4.8 % h^{-1}) than those for the algae exudates (12.1 ± 3.9 % h^{-1}) under advective conditions. Advective transport of matter induced by the stirred benthic chambers increased benthic C degradation by a factor of 8 for the coral exudates, but only doubled for the algae exudates.

Discussion

This study confirms that benthic reef algae similar to hermatypic corals release organic matter in dissolved and particulate form to their surrounding. The assumed differences in organic matter release between benthic reef algae and corals (please see introduction) are verified by the tendency that corals release more POC and algae more DOC as well as by the differences in carbon stable isotope signatures. The latter finding may be caused by a more pronounced photosynthetic C assimilation of the benthic reef algae (Fry 2006), but may also indicate different chemical composition of algae compared to coral exudates. This aspect needs further detailed chemical analyses, but the differences in natural C stable isotope signatures suggest the suitability of this material for natural tracer studies.

	Autumn 2006	
	DOC net release	POC net release
Turf	66.0 ± 23.0	2.7 ± 1.3
Caulerpa	10.0 ± 8.0	0.8 ± 0.2
Peyssonnelia	22.0 ± 18.0	2.2 ± 0.3
Acropora	105.0 ± 193.0	2.5 ± 0.6
Stylophora	-75.0 ± 45.0	7.8 ± 1.5
Pocillopora	-435.0 ± 30.0	2.8 ± 0.8
	Summer 2007	
	DOC net release	POC net release
Turf	1.46 ± 1.50	1.34 ± 0.34
Caulerpa	1.63 ± 0.81	0.48 ± 0.34
Peyssonnelia	1.57 ± 1.15	n.m.
Acropora	4.00 ± 0.70	2.24 ± 0.41
Stylophora	-3.81 ± 11.06	5.04 ± 1.77
Pocillopora	-6.75 ± 3.52	3.88 ± 0.58

Table 1: Organic matter release by the dominant benthic algae (Turf algae, green algae *Caulerpa*, red algae *Peyssonnelia*) and hermatypic corals (*Acropora*, *Stylophora*, *Pocillopora*) in the study area during the first two expeditions to the Northern Red Sea (means ± SE given as mg C m^{-2} coral or algae surface area h^{-1}; n.m = not measured; data from other expeditions not measured yet).

The comparably high DOC release by benthic reef algae in combination with the observed stimulation of planktonic microbial activity supports previously postulated statements (Kline et al. 2006, Smith et al. 2006, Dinsdale et al. 2008), which suggested that DOM released by benthic algae could stimulate microbial O_2 consumption with subsequent damage of corals in direct vicinity via hypoxia or anoxia.

Generally, algae-derived organic matter is obviously rapidly degraded in the water column, whereas this applies for coral-derived organic matter in the reef sands. Reasons for that may be that a high proportion of the algae-derived organic matter enters the DOM pool and can be taken up by planktonic microbes via the microbial loop. Kuntz et al. (2005) could demonstrate that because of this interrelationship DOM is more deleterious for corals than inorganic nutrients in reef waters.

Figure 1: Coral (upper panel) versus benthic algae dominated (lower panel) fringing reef areas in front of MSS, Aqaba, Jordan, photographed during spring expedition 2008.

Coral-derived organic matter in contrast contains more POM, which is often dominated by mucus. This material can be degraded by (specialized) microbes inhabiting the calcareous coral reef sands in high abundances (Wild et al. 2004b, Wild et al. 2005b, Wild et al. 2006), thus providing an explanation for the comparably high benthic degradation rates observed in the present study. Coral mucus in addition, because of its gel-like structure, can easily be transported via advection into the highly permeable reef sands, which act as biocatalytical particle filter systems. Such transport may not be possible to that extent for the particulate fraction of algae-derived organic matter, which can explain the pronounced advective stimulation of benthic coral-derived organic matter degradation. Algae-derived POM may in addition have a distinctive refractory character (Buchsbaum et al. 1991, Kristensen 1994), which prevents rapid degradation and leads to deposition and ultimately blockage of the reef sands. This may compromise the important function of reef sands for the recycling of organic matter and thus has potential implications for reef management.

The observed strong seasonal differences concerning algae- and coral derived organic matter release in the study area between autumn and summer were probably caused by higher availabilities of inorganic nutrients in autumn due to colder temperatures and the beginning of deep water mixing typical for the Northern Red Sea (Rasheed et al. 2002). A higher availability of inorganic matter may have resulted in increased algae growth rates and associated high synthetisation of DOM. Monitoring of benthic reef algae coverage also showed strong seasonal differences (Haas et al. unpublished data) with temporal overgrowth of reef corals by algae during late winter and early spring (see Fig. 1). However, algae blooms collapsed soon after due to depletion of inorganic nutrients in late spring. Permanent phase shifts will thus likely not appear in the study area if inorganic nutrient input from land or mariculture facilities and direct reef damage are avoided.

In summary, both investigated groups of organisms can obviously act as reef ecosystem engineers via organic matter release. However, the hard corals as “old” engineers (i.e. before phase shift) contribute differently to reef processes than benthic algae as the “new” engineers after phase shift. Element cycles via coral-derived organic matter as described by Wild et al. (2004a) contributing to the conservation of essential nutrients in the reef ecosystem will likely not take place in an algae dominated post phase shift reef, as algae-derived organic matter can apparently not substitute the important particle trapping function of coral mucus. This pilot study therefore suggests that phase shifts from coral to benthic algae may have far reaching consequences for biogeochemical processes and general reef functioning.

Abstract. The NOAA/NASA Pathfinder sea surface temperature (SST) data from 1985 to 2006 are examined for variability and trends spanning the recent 1995-98 Pacific Decadal Oscillation (PDO) reversal to look for implications to tropical ecosystems. These twenty-two years of satellite observations reveal some noteworthy shifts that differ among major ocean basin. The data also reveal expected more rapid SST increases toward higher latitudes, especially in the northern hemisphere, consistent with Intergovernmental Panel on Climate Change (IPCC) projections. Over the 22-year timeframe, most regions showed rising trends but a few regions are presently experiencing 22-year cooling trends and thus decreasing pressure from thermal stress. What will be instructive for the future of our valuable coral reef ecosystems is whether the dramatic regional shift in trends since the recent 1995-98 PDO reversal continues to persist into the second decade of the 21st Century or if the pattern becomes overwhelmed by the pattern consistent with long-term climate change.

Key words: Climate change, SST, satellites, temperature trends.

Introduction

Our tropical oceans continue to reveal regionally diverse but changing sea surface temperature (SST) patterns and trends as we move into the 21st Century. Increasingly coral reef ecosystems have been in the news due to episodic massive coral bleaching that, in many locations, has the marine conservation community concerned about the future of their valuable habitats. In 2005, the coral community witnessed another record breaking thermal stress event throughout much of the eastern Caribbean from Puerto Rico to the British and US Virgin Islands to Barbados (Wilkinson and Souter 2008); in 2004 and 2006 Kiribati experienced massive bleaching; while in 2002 the Great Barrier Reef saw another round of extensive bleaching (http://www.reefbase.org/).

With global satellite archived SSTs now spanning more than two decades, we now have sufficient data to examine their trends not only globally but also by basin. In this paper we have taken each ocean basin in its entirety over the tropical belt and then subdivided them each into their northern and southern hemispheric component. Being aware that many climatologists have established that some of the extreme variability during the 1990s can be attributed to a mid-90s reversal in Pacific decadal patterns (Mantua et al. 1997) we have also looked at the 1st half of the 22-year record and compared it with the 2nd half.

Data

In this analysis NOAA's Coral Reef Watch (CRW) updates our climate trend statistics for the tropics using 4-km resolution Version 5.0 Pathfinder daily SST data. This builds upon our previously published analyses (Strong 1998; Strong 1991; Strong et al. 2006) by incorporating four additional years of SST data and improving the resolution of our results from 50-km to 4-km. The Pathfinder SST data are produced by retrospective analysis of daily Global Area Coverage (GAC) retrievals and are available in a variety of temporal resolutions (Casey and Cornillon 1999; Kilpatrick et al. 2001). Data are available at http://www.nodc.noaa.gov/SatelliteData/pathfinder4km/.

We analyzed global satellite-derived SSTs from 35ºN to 35ºS from 1985 to 2006. Continued month-by-month comparisons of coincident *in situ* and SSTs at various locations around the global oceans reveal tight correlations and, most importantly, no biases between the buoy-measured and remotely-sensed data sets over time (not shown). Therefore we have the ability over this time period to examine our tropical oceans more completely than had been possible with *in situ* SST measurements, baring prolonged periods of cloudiness where SSTs become obscured from the view of the satellite – fortunately this is more of an issue at higher latitudes than for the tropics. Since the satellite-derived Pathfinder SSTs come from

continuous, overlapping, operational NOAA satellites, they have what we believe to be the best possible climate-quality global SST data since 1985.

In calculating SST trends for the 22-year time frame from the daily 4-km Pathfinder SSTs, we used only the daily nighttime SSTs. This was done to avoid the error caused by uneven day-night data distribution for places that experience significant diel variation in SST caused by daytime solar heating and nighttime cooling, especially during calm weather conditions. First, only high quality SST values were used (quality flag ≥ 4 as set in the Pathfinder processing — in a scale ranging from 0 to 7, lowest to highest quality) (Kilpatrick et al. 2001). The monthly mean SST at each 4-km pixel was calculated by averaging all the available, high quality daily nighttime SSTs in the 3x3 pixel box centered on the pixel where the SST is made. If a pixel contained no qualified data during a month, a missing data flag was assigned to that pixel for that particular month. Based on the resulting monthly mean SSTs, for every pixel, one round of temporal linear interpolation was conducted to fill missing monthly mean SSTs using the monthly mean SSTs of the prior and subsequent month if both are available. No further missing data filling was performed for monthly mean SSTs. Finally, our annual mean SSTs at each pixel were calculated from the 12 monthly mean SSTs at the pixel, where we required that all 12 monthly mean SSTs had to be available for an acceptable calculation of an annual mean for that year; otherwise we flagged the value as missing data for that year. SST trends were calculated from the annual mean SSTs for all pixels that had annual mean SSTs available for at least half of the total number of the years covered.

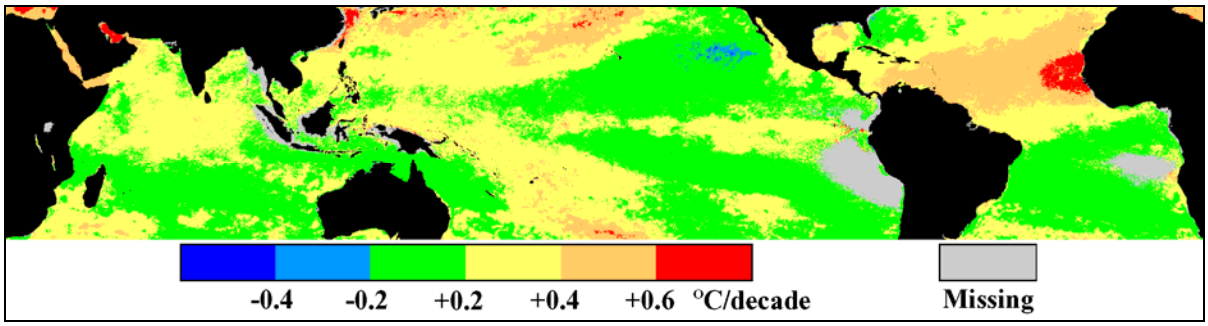

Figure 1: 22-year satellite SST Trends (1985-2006)

Global Images of Changing SSTs

In Fig. 1 we present our SST trends from monthly mean SSTs at 4-km resolution for the 22-year time frame. The pixels where the availability of SST data is not sufficient to calculate a trend, as explained in the preceding section, show up as areas of "gray" in the Fig. 1 and principally occupy areas off western S. America, west of Baja California, the region close to and surrounding Indonesia and Papua New Guinea, as well as the south Atlantic off Africa. These areas do, in fact, have persistent cloud cover that has resulted in a few months of data being hidden from the view of the NOAA satellite radiometers. Areas shown in green demonstrated weak cooling or warming (-0.2 to +0.2°C /decade) for the period while those areas depicted as more orange or red demonstrated much higher increases in SST. In the 22-year period, the entire tropical region demonstrated either warming or very slight cooling (> -2°C/decade) – except for the small "blue" (≤ -2°C/decade) region off Mexico in the northeastern tropical Pacific Ocean.

When we examine the tendencies over two 11-year intervals that straddle the mid-1990s shift in Pacific decadal temperatures, often referred to as the pacific Decadal Oscillation or PDO (Mantua et al. 1997; Bondi et al. 2001), we observe much more local variability and some fairly robust 11-year trends (Fig. 2). Whereas the earlier 11-year interval (1985-1995) shows some downward SST trends in the tropics, all of those regions (predominantly in the southern hemisphere) exhibited pronounced reversals in the following 11 years (1996-2006).

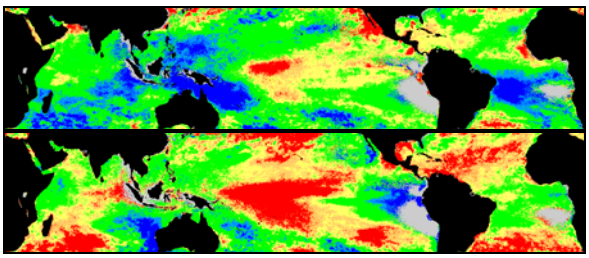

Figure 2: SST tendencies for first 11 years [top: 1985-1995] and second 11 years [bottom: 1985-1995]. Color scale as for Fig. 1.

Fig. 3 provides 22-year trends calculated from mean annual SST, both globally and divided by

hemisphere. Over 95% of the tropical ocean pixels gave cloud-free SSTs that went into these calculations. Mean tropical SSTs increased at a rate of + 0.21 °C/decade with a northern tropical ocean increase one and a half times as fast as that of the southern tropics.

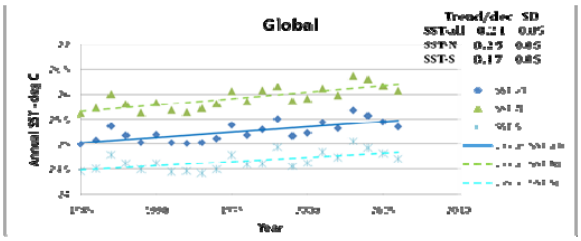

Figure 3: Tropical [35N-35S] yearly SST means with trends; global tropics and by hemisphere.

Fig. 4 plots the zonal oceanic zonal means of the 1985-2006 SST trends at 4-km resolution between 35S and 35N. For each line of latitude, the mean value is calculated from all data available at that latitudinal row.

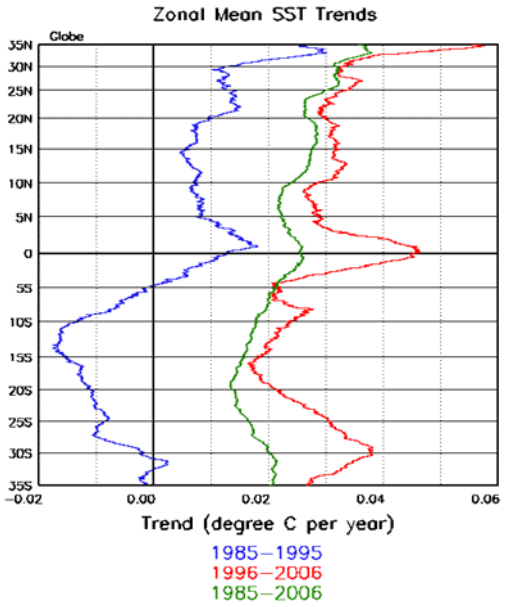

Figure 4: Trends averaged across latitudinal pixels: 1985-1996[blue], 1996-2006[red], and 1985-2006[green]

This mean row value is considered as the mean value for all of the water pixels in that row. For most rows, the percentage of missing data pixels is very low (< 5%). The y-axis, i.e., latitude axis, is not linear and is plotted in proportion to the variation of the water surface area in the meridional direction as the result of both the change in latitude and change in landmass at different latitudes.

Some Representative Virtual Station Trends

In our collaborations with marine park managers, CRW maintains a set of 24 representative operational Virtual Stations around the globe (Liu et al. 2006) spanning all ocean basins (in late-2008 an additional 166 stations were added as "experimental" Virtual Stations – http://coralreefwatch.noaa.gov). Operational stations are maintained "24/7" and the data for these stations continue from satellite to satellite as the NOAA observing system is maintained seamlessly through time, with routine verifications/calibrations preserving data quality and continuity. The new 166 sites are termed "experimental" Virtual Stations as the representativeness and final location of these sites is under evaluation. Below, the trends at some of the operational and experimental Virtual Station sites are discussed, along with some other representative sites selected that help extend this trend analysis across the tropics. Fig. 5 provides trends at these selected sites.

Caribbean – Atlantic Ocean

Four selected operational northern hemisphere, Caribbean-Atlantic Virtual Station sites are shown here (Fig. 5a). SST trends range from a low of +0.22°C/dec at Puerto Morelos and Lee Stocking Island (Bahamas) to a high nearly twice that at the US Virgin Islands.

Puerto Morelos:	+ **0.22°C/dec** [**σ** = 0.06]
USVI:	+ **0.41°C/dec** [**σ** = 0.10]
Bahamas [Lee Stocking]:	+ **0.22°C/dec** [**σ** = 0.09]
Bermuda:	+ **0.27°C/dec** [**σ** = 0.08]

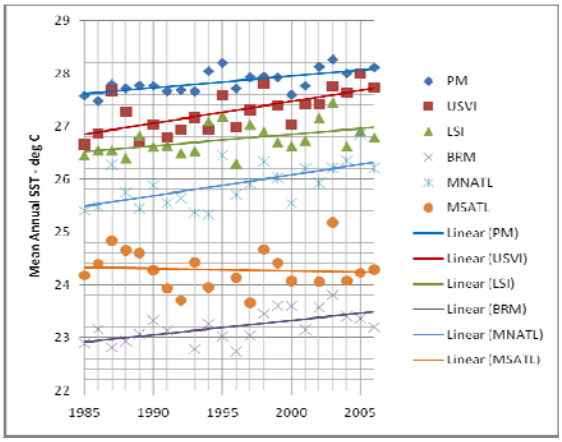

Figure 5a: Atlantic Ocean Virtual Stations

Mid-Atlantic Ocean - Extremes

Two additional middle Atlantic SST Virtual Stations were considered as mid-ocean examples on either side of the equator (Fig. 5a). Trends [as can be seen Fig. 1] are high in the North Atlantic but there is no significant trend in the South Atlantic.

Mid N. Atlantic: + **0.39°C/dec** [**σ** = 0.11]
Mid S. Atlantic: - **0.04°C/dec** [**σ** = 0.13]

Indian Ocean

The three Virtual Stations across the Indian Ocean (Fig. 5c) show the most dramatic increase in SSTs in the Seychelles, +0.30°C/dec, and lower rise of +0.19°C/dec at our Zanzibar site.

Zanzibar: + **0.19°C/dec** [**σ** = 0.08]
Seychelles: + **0.30°C/dec** [**σ** = 0.12]
Scott Reef: + **0.24°C/dec** [**σ** = 0.14]

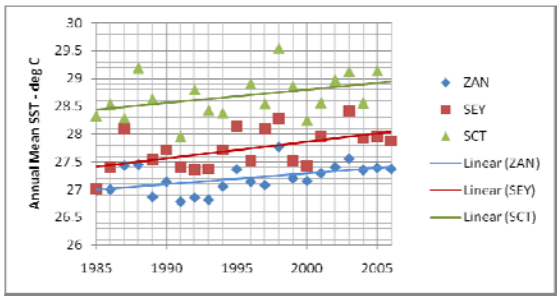

Figure 5c: Indian Ocean Virtual Stations.

Pacific Ocean

We found quite a range of increasing SST trends over the Pacific as represented by seven example Virtual Stations (Fig. 5b) from +0.38°C/dec at Bolinao, Philippines to only +0.19°C/dec at Heron Island, Australia.

Midway: + **0.34°C/dec** [**σ** = 0.17]
Guam: + **0.36°C/dec** [**σ** = 0.15]
Kiribati: + **0.20°C/dec** [**σ** = 0.25]
Palau: + **0.29°C/dec** [**σ** = 0.18]
Bolinao: + **0.38°C/dec** [**σ** = 0.17]
Heron Island: + **0.19°C/dec** [**σ** = 0.11]
Oahu: + **0.20°C/dec** [**σ** = 0.12]

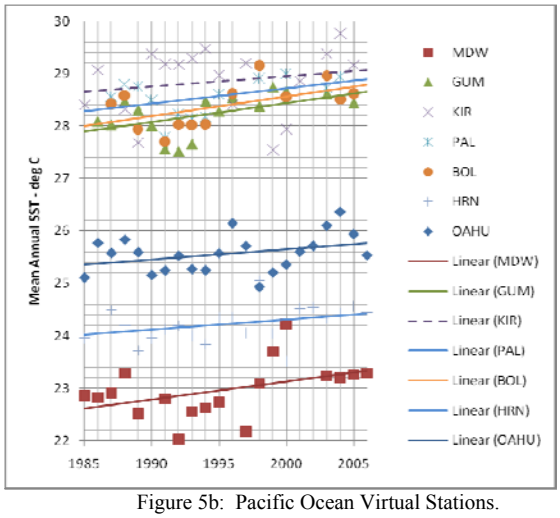

Figure 5b: Pacific Ocean Virtual Stations.

These analyses at our Virtual Stations suggest significant variability between and within oceanic basins.

Regional Trends

Examining our data by ocean basin shows interesting patterns. The greatest rate of warming has occurred in the North Atlantic. The Southern basins continue to lag behind with trends nearly half those found north of the Equator – the South Pacific rate is nearly one third that of the tropical North Atlantic, offset primarily by the weaker rises over much of the eastern portion of each region.

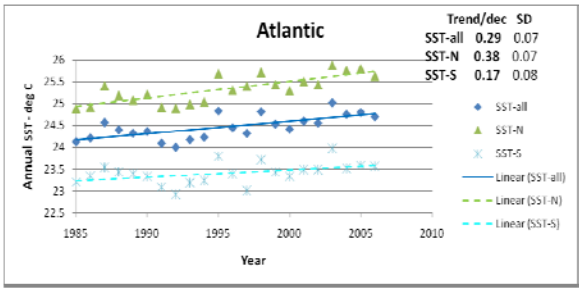

Figure 6a: Atlantic Ocean Trends.

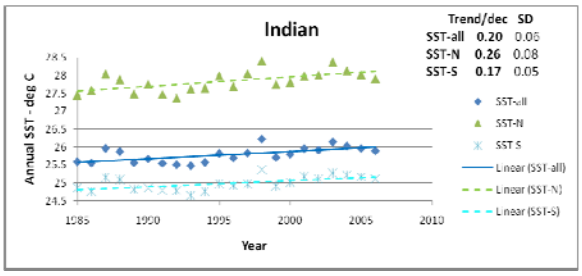

Figure 6b: Indian Ocean Trends.

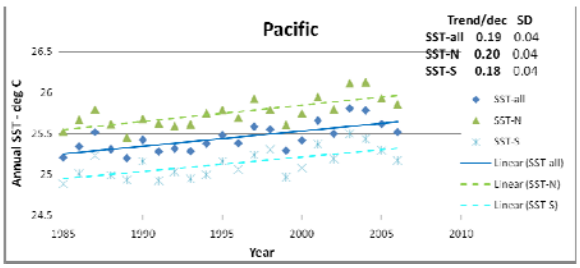

Figure 6c: Pacific Ocean Trends.

Discussion

We have presented a case for increasing ocean SSTs, first with only 8 years (1982-1989) of SST satellite data (Strong 1998; Strong 1991), then 10 years later (Strong et al. 2006), and now with 22 years of rigorously reconstructed Pathfinder SSTs. Under the growing concern for continued rising temperatures looming for the rest of this century, we can see some fairly consistent trends stabilizing with a longer

record over the global tropics. Although most of our coral reef sites tend to favor the warmer non-upwelling sides of each ocean basin (where corals grow best) and are confined within 35 degrees of latitude on either side of the Equator, they are often in regions that appear to have some of the higher warming trends in their respective basins. This would be expected since the eastern sides of each basin are more influenced by upwelling (and increased cloud cover) that introduces cooler water from below helping to stabilize our warming oceans. With convergent water movement and a tendency more toward sinking water columns in the tropics on the western sides of these basins, warmer surface waters accumulate heat in the upper layer more quickly, where these reefs thrive, thus favoring SST trends that would be expected to be larger than those of their eastern region (upwelling) counterparts.

Since the overall calculations of our tropical SST trends have missed several percent of the total sea surface area where cooler SSTs persist due to frequent persistent cloud cover, we might expect the trends for our total areas (all pixels) in each basin to be slightly less than what has been shown if we were able to incorporate these SST pixels (cloudy/upwelling) into our calculations (this will eventually become possible when satellite microwave SSTs become integrated into our observation program of SSTs).

We were able to process several years of archived operational SST annual mean SSTs (http://coralreefwatch.noaa.gov) for our Virtual Station sites to compare with the Pathfinder SSTs. These results (not shown) revealed nothing unusual and were virtually coincident giving us confidence in the accuracy of both our operational SSTs and re-processed Pathfinder SSTs. These results all consistently point out that coral reefs are already experiencing rapid temperatures increases beyond those to which they may be able to adapt (Donner et al. 2005; Hoegh-Guldberg et al. 2007).

An interesting finding that can be seen in each of the three tropical ocean basins is that 2003 has been our warmest year of the 22-year record. Since that time SSTs have been gradually dropping, indicating a downward shift from the long-term trend. If this is a result due to the recent PDO reversal there might be some hope for our thermally stressed ecosystems. 17 of our 24 Virtual Stations showed cooler than normal SSTs during the first half of 2008, including some of the lowest monthly values seen this century! If this reduced short-term trend continues to prevail there is a glimmer of hope for many of our coral reefs for the next decade or two. The long term concern is the path of temperatures after the next PDO reversal, perhaps in the mid-2010s, when SST increases might surpass those seen during the 80s and 90s reaching yet higher levels of thermal stress (Hoegh-Guldberg et al. 2008). Based on our results and continued trends, unless coral reefs are able to develop coping mechanisms for increased thermal stress during the next decade, the flowing decades will only continue to put our fragile reefs under increased concern.

Abstract. Recent evidence suggests that, as global climate changes and seawater temperatures rise, the primary cause of coral bleaching is zooxantheallar mortality indicated by cell apoptosis/necrosis. But are the coral hosts themselves sensitive to increasing temperatures, and, if so, to what degree? We exposed the coral *Favites complanata* (Ehrenberg, 1834) with their symbiotic zooxanthellae (*Symbiodinium* sp.) to experimental temperatures of 28 (control), 30, 32, and 34°C for 12h. We assessed coral and symbiont cells *in situ* for symptoms of apoptosis and necrosis using transmission electron microscopy (TEM). *F. complanata* host cells *in situ* exhibited little or no mortality from exposure to increased seawater temperatures, except at very high temperatures (34°C) for ≥12hrs. By contrast, we found high levels of apoptosis/necrosis in the zooxanthellae *in situ* under all experimentally elevated temperatures. These findings indicate that the host corals are adapted/exapted to seawater temperature increases. They also imply that the coral hosts do not suffer mortality from temperature stress but from loss of their symbionts – a process driving natural selection in *Symbiodinium* and most likely resulting in their rapid adaptation to a changing environment.

Key words: Adaptation, Apoptosis, Bleaching, Exaptation, Necrosis, Seawater temperature, *Symbiodinium*

Introduction

Concerns are growing as climate change and associated increased seawater temperatures continue to induce coral bleaching in the tropics and sub-tropics (Sheppard and Rioja-Jieto 2005; Baker et al. 2008). Coral bleaching, a process by which corals lose their algal symbionts called zooxanthellae (genus *Symbiodinium*), is a response to heat-stress where temperatures rise above the maximum tolerance of the zooxanthellate corals/holobionts (Hoegh-Guldberg 1999). Such variation in temperature may be an important selective factor in the evolution of the relationship between corals and their endosymbionts. Some investigators suggest that the loss of *Symbiodinium* cells may help corals adapt to changing environmental conditions by allowing them to "shuffle" (Buddemeier and Fautin 1993) their complement of zooxanthellae, benefiting the corals (the "adaptive bleaching hypothesis"; also see Kinzie et al. 2001). Others believe that *Symbiodinium* shuffling does not occur quickly enough (Hoegh-Guldberg et al. 2002), serving to prolong the eventual death of the host. The interim survivorship period may last for up to six weeks. Grottoli et al. (2006) have demonstrated that *Montipora capitata* can replenish its energy reserves and biomass in the absence of its symbionts by increasing its food intake five-fold after temperature-induced bleaching. Borell et al. (2008) found similar effects in *Stylophora pistillata* (Esper) and *Galaxea fascicularis* (Linnaeus).

Recent data have indicated that bleaching is a primary selective factor for zooxanthellae, causing very high levels of mortality in zooxanthellae *ex situ* (Strychar et al. 2004 a, b; 2005). This can be inferred from the 95-99% mortality rate of zooxanthellae expelled from scleractinian and alcyonacean corals exposed to temperatures of 32-34°C for 9-48 h (*ibid.*).

Survival of zooxanthellae exposed to high seawater temperatures may occur as a result of adaptation by ancestors that have survived prior exposure to these conditions. Survival may also be occurring due to exaptation to these temperatures. Exaptation is defined as a character that has evolved for another function, or no function at all, but which has been co-opted for a new use (Gould and Vrba 1982, cf Futuyma 1998; McLennan 2008; also see Strychar and Sammarco, 2009). Mettler and Gregg (1969) discuss exaptation, previously termed "pre-adaptation", as follows: "…populations can… generate many genotypes with varying degrees of adaptedness. Those [non-adapted] forms produced each generation…are weeded out by selection, but …are continuously produced and …considered to be 'stores on hand'…the progenitors of future generations in the event of a changed environment. They are 'pre-adapted' genotypes ready for new

situations which might be met by the population…."

The high mortality rates observed by Strychar et al. (2004a,b, 2005) were determined *via* assessing apoptosis and necrosis in the symbiont cells. Apoptosis is a genetically pre-programmed, physiological and biochemical event that leads to the removal of unwanted and/or abnormal cells (Strychar et al., 2004a). This helps to regulate abundant cell populations. Apoptosis is not a synonym for programmed cell death, which involve other mechanisms (e.g. paraptosis, pyroptosis, etc.; see reviews of Ameisen 2002; Fink and Cookson 2005). Necrosis, by contrast, is a passive, accidental, and unordered occurrence of cellular death (Strychar et al., 2004a), causing inflammation of host tissue. For example, increased production of apoptotic cells in mammalian hosts elicits removal of dead/dying cells *via* phagocytosis, preventing inflammation. Necrosis, on the other hand, causes uncontrolled inflammation (Fink and Cookson, 2005). In Cnidarians, increased concentrations of necrotic cells likely cause similar responses. In zooxanthellate corals, the occurrence of apoptosis or necrosis in the symbiont but not the host would indicate that the former is more sensitive to a perturbation than the latter.

The rate of coral mortality due to bleaching is believed dependent upon the severity (intensity and duration) of the temperature anomaly (Winter et al. 1998, 2006; Craig et al. 2001; but also see Podesta and Glynn 1997). We have shown that some host corals, specifically *Acropora hyacinthus* (Dana, 1846; Acroporidae) and *Porites solida* (Forskål, 1775; Poritidae) from the Great Barrier Reef, Australia have a much broader temperature tolerance than that of the zooxanthellae and exhibit adaptation/exaptation towards increased temperatures (Strychar and Sammarco, 2009). The zooxanthellae appear to be doing most of the adaptation within this co-evolved symbiotic relationship. Here we demonstrate that this phenomenon is not restricted to these two species, or families, but may be extended to *Favites complanata* (Ehrenberg, 1834; Faviidae), and that this adaptation / exaptation may be a common characteristic within the Scleractinia.

Material and Methods

Forty colonies of *Favites complanata* were collected at ~8.5m depth from Barren Reef (23°10'S, 151°55'E), Great Barrier Reef, Qld, Australia. Colonies were exposed to different experimental seawater temperatures, following a random blocks design (Zar 1998). Full details of the experimental design may be found in Strychar et al. (2004b) but will be summarized here. Filtered seawater was pumped through 10 and 1µm filters and deposited into a series of header tanks (total combined vol = 1000 l), mixed using submersible pumps. Water was then pumped to 8 two-liter plastic holding chambers at a constant flow rate of 20ml min^{-1} through 1µm Millipore® filters. Magnetic stir bars provided water movement within each chamber. Colonies were subjected to experimental temperatures of 28 (control), 30, 32, and 34°C for 12h. Ten replicate (n_i=10) coral fragments were used for each temperature. Data presented here are derived from experiments described in Strychar et al. (2004b); here, however, the focus has shifted to host and *Symbiodinium* cells *in situ*, as opposed to expelled cells. We acknowledge that the rates of temperature increase and/or time scales of exposure employed here are faster and/or shorter than may occur naturally in the reef environment. Hence, the coral and symbiont experimental responses may not be representative of a protracted natural bleaching event.

In these experiments, coral tissue (~5mm^2) was excised from a colony using a scalpel and fine dissecting forceps at the 3, 9, & 12h marks. A solution of sodium citrate (10%) and formic acid (20%) was used to decalcify skeletal tissue (Strychar and Sammarco, 2009). Any skeletal tissue remaining after 24h was gently crushed using a micro-tissue grinder, and the solution was centrifuged and washed 3x in phosphate buffered saline solution (PBS). Following a 3rd wash and removal of the supernatant, samples of host tissue, along with the symbiont cells, were embedded in 0.2ml of agar. Thus, both the symbiotic partners could be analyzed simultaneously. After solidification, samples were post-fixed in 1% osmium tetroxide in 0.1 M PBS for 24h at 48°C. They were then centrifuged (500x *g*) and the supernatant removed. At 30 min intervals, the samples were dehydrated in a graded series of acetone washes (30, 50, 70, 90, & 3x at 100%). The embedded samples were then suspended in a series of graded acetone–Spurr's resin to ensure infiltration of resin into the tissue. Samples were finally polymerized into a mould by incubation at 60°C for 3d.

An Ultracut T microtome was used to prepare thin sections of tissue, which were placed on 3mm copper grids coated with 1.2% (w/v) formvar in trichloro-methane. Aqueous uranyl acetate was then used to stain the thin sections for ~5 min, followed by staining with 1.5% (w/v) lead citrate for 5 min. The ultrastructural characteristics of each thin section were observed with a JEOL-1010 or Hitachi 7000 transmission electron microscope (TEM) and analyzed for ultrastructural symptoms of apoptosis, necrosis, and viability. Thin sections were examined during each sampling period; 100 host and 100 symbiont cells were randomly sampled per section per experimental temperature treatment at each time interval. Frequencies of each were calculated.

Cells exhibiting apoptosis were characterized by cell contraction, chromatin condensation, and cell fragmentation into membrane-bound fragments called apoptotic bodies (see Strychar et al., 2004a). Necrotic cells were identified by cellular and organelle swelling, eventually causing release of the cytosolic contents into the surrounding host tissue.

Results

Coral host and* Symbiodinium *cells – Main Effects

TEM successfully detected variation in host and *Symbiodinium* cell states under varying seawater temperatures. There was no significant difference in apoptosis and necrosis levels between the 28°C and 30°C treatments in either the *Favites complanata* host cells or the *Symbiodinium* cells ($p>0.05$, MANOVA). Apoptosis levels increased significantly, however, in host corals exposed to temperatures ≥32°C (main effects; $p<0.05$, MANOVA). Levels of necrosis in host cells did not change significantly under conditions of increased temperatures *in situ* ($p>0.05$). Endosymbiont cells exhibited significantly higher levels of apoptosis at temperatures >30°C ($p<0.05$). Necrosis was significantly more frequent in the symbionts at temperature treatments >30°C *vs.* 28°C (control). Symptoms of stress in host corals and their symbionts (i.e. apoptosis & necrosis) rose significantly >9h after initiation of the experiment (main effect – time; $p<0.05$, MANOVA).

Temporal Responses of* Favites complanata *host cells and symbiont cells* in-situ *at 28-34°C. At 28°C, both host and symbiont cells exhibited high percentages of viability *in situ* (Fig. 1). The number of viable symbiont cells, however, decreased markedly and significantly as experimental temperatures were increased from 28 to 34°C ($p<0.001$, Tukey HSD and Bonferroni; Fig. 1).

Fig. 2 illustrates how the frequencies of apoptotic cells in both host and symbionts were negligible at experimental treatments of 28-30°C through time. At 32°C and 34°C, however, the level of apoptosis increased significantly through time in the *Symbiodinium* cells ($p<0.001$, Tukey HSD and Bonferroni tests). The frequency of apoptosis in *Favia complanata* host cells *in situ* rose significantly only under the extreme experimental temperature of 34°C, when compared to the control ($p<0.05$).

The frequency of necrosis in the host cells *in situ* did not vary significantly between any of the experimental temperatures ($p>0.05$, Tukey HSD and Bonferroni tests; Fig. 3). By contrast, *Symbiodinium* cells exhibited significantly higher frequencies of necrosis at 34°C ($p<0.04$; Fig. 3).

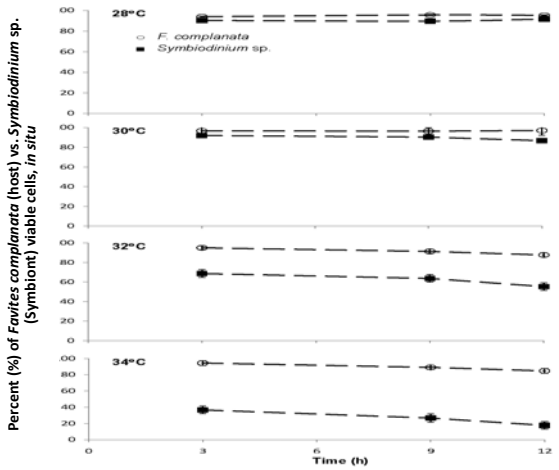

Figure 1: Effect of temperature on the relative frequencies of **viable** *Favites complanata* host and *Symbiodinium* cells *in-situ,* collected over 12h. Data are presented as the mean plus 95% confidence intervals from nine separate experiments; some confidence limits, too small to be seen. Each point = percentage of different cell types. The frequency of viable cells in *Symbiodinium* at 32°C and 34°C treatments were each significantly lower than all other treatments ($p<0.05$, Tukey HSD test). There was no significant difference between the 30°C and 32°C treatments in the host coral ($p>0.05$), no significant difference between the 28°C and 30°C treatments, and the 34°C treatment was significantly lower than the other treatments ($p<0.05$). There was an significant decrease in frequency of viable cells in both *Symbiodinium* and in the host cells between 3 and 12 hrs ($p<0.001$ & $p<0.05$, respectively).

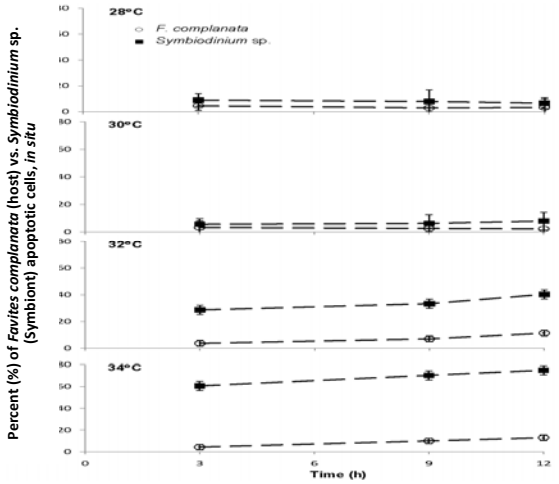

Figure 2: Effect of temperature on the relative frequencies of **apoptotic** *Favites complanata* host cells and *Symbiodinium* cells *in-situ,* collected over 12h. Data presented as the mean plus 95% confidence intervals; some confidence limits, too small to be seen. Each point = percentage of different cell types. The apoptotic cell frequencies in *Symbiodinium* at 32°C and 34°C were each significantly higher than all other treatments ($p<0.05$, Tukey HSD test). There was no significant difference between the 28°C and 30°C treatments ($p>0.05$). Apoptotic cell frequencies in the host cells were significantly higher at 34°C than at 28°C and 30°C ($p<0.05$). There was no significant difference between the 28°C and 30°C treatments ($p>0.05$). There was a significant increase in apoptotic *Symbiodinium* cells between 3 and 12hrs ($p<0.05$), but no difference in the host cells during this period ($p>0.05$).

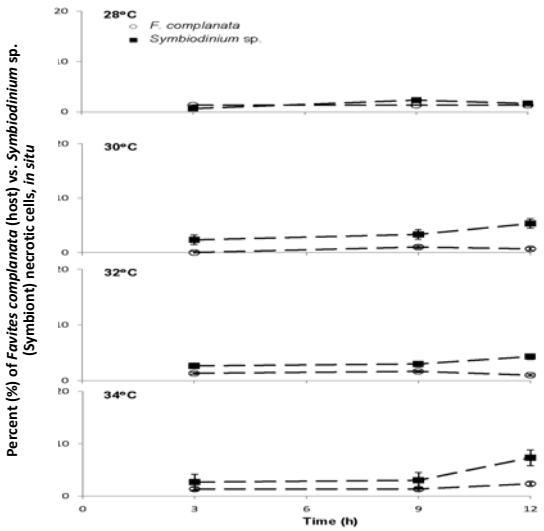

Figure 3: Effect of temperature on the percentage of **necrotic** *Favites complanata* host cells and *Symbiodinium* cells *in-situ,* collected over 12h. Data are presented as the mean plus 95% confidence intervals; some confidence limits, too small to be seen. Each point = percentage of different cell types. The frequency of necrotic cells in *Symbiodinium* at 34ºC was significantly higher than at 28ºC ($p<0.05$, Tukey HSD test). There was no significant difference in necrotic host cell frequencies between any temperature treatments ($p>0.05$). There was a significant increase in necrotic *Symbiodinium* cells between 3 and 12hrs ($p<0.05$), but no significant change in necrosis in host cells during that period ($p>0.05$).

Discussion

Our data indicate that the scleractinian coral *Favites complanata* is less heat-sensitive than its endo-symbionts. We hypothesize that increasing seawater temperatures, characteristic of global warming associated with climate change may be acting as a selective factor on the symbiotic zooxanthellae within the coral host, but not on the coral hosts themselves. This is because the coral hosts are already either adapted/exapted to high seawater temperatures. We have already desmonstrated adaptation/exaptation in the host corals *Acropora hyacinthus* and *Porites solida* - families Acroporidae and Poritidae, respectively. The data here show that this characteristic is restricted not only to these two species or families – but may also be extended to *Favites complanata* and its family – the Faviidae, suggesting that such temperature tolerances may be a widely distributed character in Scleractinain corals.

Like earlier studies, this suggests that it is the zooxanthellae that are responsible for doing most of the dying in this symbiotic relationship and the lion's share of the adaptation to rising seawater temperatures, certainly in the central Great Barrier Reef region. We propose that mortality is much more frequent and severe in the zooxanthellar populations during bleaching, and that the corals are suffering not from heat stress but from loss of their symbiotic partners. This is consistent with the results of Mise and Hidaka (2003) who studied effects of increased temperature on *Acropora nasuta*. They described rapid degradation of zooxanthellar cells under similar conditions, detailing symptoms characteristic of apoptosis and necrosis (also see Strychar et al., 2004a), and suggested that "degraded zooxanthellae are produced by host digestion". This implies that the host controls the disposal of the compromised portion of the zooxanthellar population *in situ*. Based on our data, we believe this may be the case.

Whether seawater temperatures rose above 32°C in the evolutionary past of the host animals, or whether the genes responsible for this tolerance originally applied to some other function, is not known. Their current function, however, is clear. *Symbiodinium* appears to still be adapting to current increases in SSTs, at its own rate. Can adaptation occur in both the host and the symbiont? We believe so. The literature suggests that it is quite possible for the algal symbionts to become adapted to these changes. For example, corals and their symbionts are known to thrive in environments in the Red Sea where SSTs routinely reach 34°C (Ateweberhan et al., 2005) and salinities reach up to 40.5ppt (Karako-Lampert et al., 2004).

If our higher temperatures were approached at a slower rate, this could have allowed time for some symbiont shuffling, lessening symptoms of bleaching. This could have decreased levels apoptosis/necrosis in the symbionts when higher temperatures were reached. The effects of slow temperature increases on symbiont shuffling, however, remains to be demonstrated, in the field or lab.

Here we have considered only *in situ* cells. Earlier (Strychar et al., 2004b), we demonstrated that *Symbiodinium* cell fractions expelled from the host exhibited apoptotic or necrotic characteristics with increased seawater temperature and time (up to 48h).This further supports the concept that the host cells are better adapted to elevated temperatures than their symbiotic zooxanthellae. We have also reported that we could only identify one clade of symbiont in *Favites complanata* - clade C (Strychar et al., 2005). Not all *F. complanata* have the same clade of symbionts, however. *Symbiodinium* clades A, B, C, D (Baker and Romanski 2007), and C3 (LaJeunesse et al., 2003) have all been identified from members of the Faviidae. It is possible that *F. complanata* could associate with multiple symbiont clades; thus, the response observed in our experimental colonies may not be representative of all *F. complanata* holobionts.

The adaptation/exaptation of a host coral to elevated seawater temperatures has now been demonstrated in three different hermatypic corals

from three separate families – the Faviidae, Acroporidae, and Poritidae – from the Great Barrier Reef. These corals and possibly families of corals are either already adapted to tolerate high temperatures from their ancestors having survived past high-temperature events in their evolutionary history, or they are exapted (Gould and Vrba, 1982; cf Futuyma, 1998; McLennan 2008) to these high temperatures *via* a pre-existing character associated with another physiological function. In the case of exaptation, it is not possible to discern from what character this tolerance may have been derived.

We thus hypothesize that this character is widespread among the Scleractinia of the Great Barrier Reef, and that death of the coral host in these organisms is due to their dependency upon the nutrients or other benefits that the symbionts provide. Coral hosts appear to be well adapted to temperature stress, while their endosymbiotic zooxanthellae either die or experience irreversible cell damage while still embedded in the coral host tissue, prior to expulsion from the coral. If the symbionts are not replaced or the loss of nutrients is not supplemented within some given time period, the host may die.

Adaptation and physiological tolerance to higher than normal temperatures while maintaining normal cell and tissue function is the key to survival in both the host corals and their symbiotic zooxanthellae. It would appear that it is the inherited adaptation or exaptation of pre-existing physiological traits from some ancestor that will permit survival of corals through its application to an environmental stress, the severity of which is increasing with time.

2) Embry Riddle Aeronautical University, 600 S. Clyde Morris Blvd., Daytona Beach, Florida 32114, USA

Abstract. The objective of this study is to demonstrate that an efficient instrument for conducting surveys and inventories of coral reefs to assess those ecosystems at higher risk and develop mitigation strategies is through the use of a Geographic Information System (GIS). Efficient monitoring requires the assessment of various coastal data baselines and the evaluation of subsequent alterations in spatial patterns. While monitoring involves real-time components, among the most powerful tools of a GIS are its modeling capabilities, which allow simulation of various climate change scenarios. Relevant aspects include changes in coastal land use, wetlands, and shoreline configuration. Using Caribbean coral reef examples, the results of this research reveal that GIS techniques and applications play an integral role in defending coral reefs from climate change and other threats. Planners and politicians require the ability to analyze risks, assess impacts, and consider alternatives based on input from researchers across diverse disciplines. GIS provides the collective tool that integrates multifaceted data and transforms it into a meaningful medium for informed decision-making.

Key words: Geographic Information Systems, reef monitoring, reef management

Introduction

According to the most recent assessments from the Intergovernmental Panel on Climate Change (Mann & Kump 2009), as a result of climate change and sea level rise, the planet's coasts are exposed to multiple risks including coastal erosion, changes in sediment and nutrient transport, and additional coastal flooding. Heavily populated, low-lying areas, which already face other challenges such as tropical storms or local coastal subsidence, are especially vulnerable. Coastal wetlands, including mangroves and salt marshes, will be impacted by sea-level rise especially in places where they are inhibited from migration as a result of natural or anthropogenic barriers. Despite their diversity, coral reefs are highly susceptible to thermal stress and have low adaptive capacity. Increases in sea surface temperature of 1 to 3 degrees Celsius are projected to result in more frequent coral bleaching events and widespread mortality with increasing human-induced pressures on coastal areas aggravating these negative effects. A Geographic Information System (GIS) is a tool that can create, analyze, and display sea level rise scenarios helping managers address the negative effects of elevated sea levels by allowing them to identify coral reef communities that are at risk, assess the situation, and develop mitigation strategies.

Coastal Ecology and Economy

According to Cohen et al. (1997), 20% of the people in the world live within 30 kilometers of the coast and it is predicted that by the year 2100, approximately 600 million humans will live on coastal floodplains lower than the 1000-year flood stage (Nicholls & Mimura 1998). Burns (2000) reached similar conclusions regarding island populations reporting that most island inhabitants, along with their infrastructure and socioeconomic activities, are situated just a few hundred meters from the shore and as a result, are likely to experience negative impacts from rising sea-levels. The destructive effects could include coastal flooding, loss of wetlands, saltwater intrusion, increased erosion, and higher storm surges. Additionally, these impacts have the potential to affect many of the smaller islands in the Caribbean due to certain similar traits these islands share such as limited funds, natural resources, geographic size, and infrastructure (Leatherman 1997).

Granger (1997) states that the projected sea level rise could seriously damage the socioeconomic growth of smaller island states while Leatherman (1997) asserts that practically every social and economic sector will be disrupted. Smaller low islands might not have the physical size to deal with rising sea level, and residents might be forced to relocate to other countries, which could have dire socioeconomic costs (Nicholls & Mimura 1998). For example, the IPCC (2001) projects that on the island of Cuba a 1-meter rise in sea level would displace 50,000 people. Nicholls et al. (1999) suggest that 22% of coastal wetlands could be lost as a result of rising sea levels by the year 2080 and that the Caribbean Islands along with those of the Pacific and Indian Oceans will experience the greatest relative

rise in frequent flooding. Over the past 15 years, some beaches on Trinidad and Tobago have reported annual erosion rates of 2-4 meters, which is primarily attributed to rising sea levels (Singh 1997).

Flooding and erosion also could adversely affect the tourism industry, which is a major economic sector on many islands of the Caribbean through the loss of beaches, saltwater intrusion, infrastructure damage, and other forms of degradation. Most of the islands with economies based primarily on tourism tend to concentrate their resources and infrastructure along the coasts where rising sea levels will have the greatest impact. The problem will be compounded by the fact that many existing tourist facilities currently are not adequate and frequently experience problems such as water shortages.

Many of the Caribbean Islands meet their water demands through an exclusive source such as rainwater, groundwater, importing, or surface reservoirs, which makes them vulnerable to a disruption in supply. For those islands that rely on precipitation stored during the rainy season, any variation in climatic patterns could be critical. The IPCC (2001) points out that on Barbados three months of the rainy season account for all of the groundwater recharge and, just 15% to 30% of the yearly precipitation actually makes it to the aquifer.

However, perhaps the most critical concern is the threat of saltwater intrusion, which is occurring on some islands, such as Barbados, due to over pumping. With an increase in sea level, intrusion could take place at pumping stations further inland as well as along the coasts. On Trinidad and Tobago, over pumping, which has been aggravated by rising sea levels, has contributed to a significant salinity increase among some coastal aquifers (Singh 1997).

Mangrove forests are an integral component of the island ecosystem offering protection from high tides and storm surges, while providing feeding grounds for numerous species juvenile fish and products. However, many mangrove habitats in the Caribbean are suffering from human exploitation and will face further stress with rising sea levels. According to the IPCC (2001), 62% of the mangroves in Puerto Rico have been eradicated due to anthropogenic activity, and a 1-meter sea level rise in Cuba could destroy 30% of that island's mangrove ecosystems. Alleng (1998) reports that due to the inability to migrate, Jamaica's Port Royal mangrove forest could be totally devastated with rising sea levels. Consequently, the loss of mangrove forests will have negative effects on local wildlife. For example, Sattersfield et al. (1998) observe that the forested areas of the Caribbean are home to most of the threatened bird species in the region.

Likewise, coral reefs supply food and shelter for marine flora and fauna while providing a natural barrier as well as income in the form of tourism and fishing for the Caribbean islands. However, a global inventory of Earth's coral reefs estimates that already nearly 60% are at risk due to the actions of humans (Bryant et al. 1997), and 90% of all living reefs have been damaged by coral bleaching (Goreau & Hayes, 1994). Regionally, the occurrence of coral bleaching will be the highest in the Caribbean and could take place on an annual basis over the course of the next 30-50 years (Hoegh-Guldberg 1999).

GIS Modeling and Mitigation

Among the steps that can be taken toward informing the public of these threats is the modeling of various sea-level scenarios using GIS. Beginning with the establishment of mean sea level for a particular location based on topographic quadrangle contour lines, which are the most valuable data for determining which locations might be inundated, it is possible to adjust sea-levels according to estimated rates of increase. As a result, the user can project future high water marks revealing areas under the potential threat of flooding.

The Environmental Protection Agency (EPA) has created a GIS using the United States Geological Survey's (USGS) 1-degree digital elevation series and the National Oceanic and Atmospheric Administration's (NOAA) digital shoreline data to produce a series of maps illustrating coastal areas below the 1.5-meter and the 3.5-meter contours for the eastern United States. The results suggest that approximately 58,000 square kilometers of coastline along the Atlantic Ocean and the Gulf of Mexico lie below the 1.5-meter contour and face the possibility of being flooded within the next two hundred years if sea level rises at a rate of 0.75 meters per century.

A similar GIS has been developed for south Florida that incorporates elevation and land use data to depict those areas with elevations of less than 5 feet and 10 feet. The GIS reveals that significant urban areas in Miami-Dade County could undergo flooding during high tide or storm surge events. A large portion of the Florida Keys have elevations below 5 feet that are at risk of inundation should sea levels increase at the rates predicted by the IPCC and other researchers.

Digital Elevation Models (DEM) and Triangulated Irregular Networks (TIN) also are being used to create three-dimensional GIS of areas that might be at risk as a result of rising sea levels. Three-dimensional visualization of such models allows the user to zoom and rotate the scene from a variety of angles for a better comprehension of the negative impacts associated with sea level rise. This technique can be

especially effective when presenting inundation scenarios to administrative officials and the public.

Once the potential high water areas have been delineated, a GIS can be further developed to integrate a variety of related applications, such as surveys, inventories, monitoring, and modeling. Surveys and inventories of coastal ecosystems, including coral reefs, mangrove forests, and other biota can be incorporated into a GIS to assess those ecosystems at higher risk. Other surveys that are useful for determining vulnerability along coasts consist of population distribution such as residential, commercial, and recreational areas. Similarly, the infrastructure that supports these centers such as power generation and fresh water sources should be added to the GIS.

Efficient monitoring requires the assessment of various coastal data baselines and the evaluation of subsequent alterations in spatial patterns through the use of GIS. Relevant aspects might include changes in coastal land use, wetlands, and shoreline configuration. While monitoring involves real-time components, perhaps the most powerful tool of a GIS is its modeling capabilities allowing the user to simulate sea level rise scenarios while offering complete control over the conditions of the simulations which are made affordable and manageable through the use GIS.

GIS Coral Reef Applications

Numerous environmental organizations already make use of GIS as a principal tool in their protection arsenal. According to the website of the Center for Coastal Monitoring and Assessment (CCMA) at http://ccma.nos.noaa.gov, the mission of the CCMA is to assess and forecast coastal and marine ecosystem conditions through research and monitoring. The CCMA assesses the impacts of climate change on coastal ecosystems through various means such as remote sensing and GIS. Projects include habitat mapping, especially in coral reef environments. The GIS is used to assess the baseline conditions of each coral reef and monitor any changes. Among the goals of the CCMA is to develop a GIS of the benthic habitats of all coral reefs within U.S. waters, including territories as well as an assessment of reef fish ecologies. The CCMA already has mapped essential fish habitats of the U.S. Caribbean and provided color aerial photographs of near shore waters of Puerto Rico and the U.S. Virgin Islands.

However, perhaps the greatest contribution by the CCMA is the production of comprehensive, detailed maps of 2,360 sq km of the shallow-water benthic habitats of the Northwestern Hawaiian Islands. The products include a web site and CD-ROM that provide access to digital GIS data, maps, and satellite imagery depicting the location and distribution of shallow-water coral ecosystem habitats. The GIS maps are characterized by unprecedented detail and represent the first comprehensive assessment of benthic habitats of the shallow water environments of the islands. Efforts also are underway to update the coral ecosystem habitat maps of Florida. The CCMA is an outstanding example of an organization using GIS to provide the best available scientific information for resource managers and researchers as well as offering technical advice and easy accessibility to data.

Similarly, ReefBase is the official database of the Global Coral Reef Monitoring Network (GCRMN), as well as the International Coral Reef Action Network (ICRAN). The ReefBase Project is housed at the WorldFish Center in Penang, Malaysia, with funding through ICRAN from the United Nations Foundation (UNF). According to their website at http://www.reefbase.org, ReefBase gathers available knowledge about coral reefs into one information repository. It is intended to facilitate the analyses and monitoring of coral reef health and the quality of life of reef-dependent people, and to support informed decisions about coral reef use and management.

The website outlines numerous objectives of ReefBase which include developing a relational database and information system for structured information on coral reefs and their resources that will serve as a computerized encyclopedia and analytical tool for use in reef management, conservation, and research. Additionally, ReefBase collaborates with other national, regional, and international databases, and GIS facilities relating to reefs to provide a means of comparing and interpreting information at the global level.

The ReefBase online Geographic Information System (ReefGIS) allows the user to display coral reef related data and information on interactive maps. The ReefGIS offers layers with data related to the location of reefs by type such as barrier reef, fringing reef, patch reef, and shelf reef as well as reef geomorphology and reef depth. Other layers depict coral diseases, coral bleaching, and sea surface temperatures. There is even a layer of reefs that are currently being monitored and the name of the organizations charged with the task.

Among the most noteworthy undertakings by ReefBase is the development of the Millennium Mapping GIS. Using high-resolution Landsat images, ReefBase is collaborating with NASA and other partners to create the first global uniform map of shallow coral reef ecosystems. The full image archive and the GIS shapefiles are available through ReefBase to provide high-quality information about reef location, distribution, and extent.

The Caribbean Reefs at Risk map server at http://coralreefs.nbii.gov/reefsatrisk provides spatial information about coastal areas and human threats to coastal ecosystems for the wider Caribbean Region. Most of the data come from the Reefs at Risk in the Caribbean project sponsored by the World Resources Institute and from the University of the West Indies Caribbean Coastal Data Center. Reefs at Risk supports a GIS map analyzer, which allows interactive viewing of a wide range of spatial data on coral reefs, population, development, physical components, and is capable of modeling threats to the Caribbean reefs.

The Reefs at Risk in the Caribbean project was initiated to raise awareness about threats to coral reefs and to provide detailed information about threats in specific locations across the Caribbean region. These data are available on the map server along with an index of integrated threats. The Reefs at Risk in the Caribbean project also includes an assessment of the economic benefits associated with coral reefs and of economic losses as a result of coral reef degradation. Additionally, the project offers recommendations for preserving coral reef ecosystems.

Conclusion

Long-term studies are needed in order to develop a full understanding of the composition, structure and functioning of coral reefs. Such research includes the monitoring of coral reefs and enables the tracking of changes in the health, species composition, and functioning of these diverse and delicate ecosystems.

The optimal means of managing spatial data is through a GIS, which is capable of producing maps that incorporate numerous layers of interdisciplinary data. Data gathering, modeling, and dissemination through the use of GIS offers a tool for decision-making concerning coral reefs at every level. The small representative sample of organizations and institutions dedicated to coral reef conservation presented in this paper is intended to support the claim that GIS is a powerful tool with extensive spatial data analysis capabilities that can reinforce the process of coral reef protection and policy-making, as well as long-term integrated resource management.

Biodiversity of reefs: inferring from sparse data

D.G. Fautin

Department of Ecology and Evolutionary Biology, and Natural History Museum, University of Kansas, Lawrence, Kansas 66045 USA

Abstract. Data on occurrences of a particular organism from publications and museum specimens can be used to infer occurrence of members of that species in places where sampling has not been done and at times in the past and future. Programs to make such inferences are based on knowledge of the habitat correlates of the species and determining where else in the world those habitat parameters occur. Precision of such an inference depends on 1) accurate and precise knowledge of the species' habitat requirements, 2) detailed spatially-explicit environmental data, and 3) comprehensive taxonomic and nomenclatural information. Such inferential tools can be important in understanding biogeographic consequences of climate change, in predicting where invasive species might persist, and in recognizing invasive species.

Key words: biogeographic modeling, habitat requirements, taxonomy.

The problem

Species range maps like those in many field guides (eg that to anemonefishes and their hosts by Fautin and Allen 1992, and that to marine life of southern Africa by Branch et al. 2005), are abstractions of the places where members of the species of concern are known to occur. Although the open Indian Ocean between Sumatra and Sri Lanka is depicted by Fautin and Allen (1992) as being within the range of the sea anemone *Heteractis aurora* (Fig. 1), one could not actually find the animal there because, as Fautin and Allen (1992) point out, these animals are confined to shallow water. Thus they occur along land, in strips so narrow they are not easily indicated on small-scale maps – so the range is represented as covering the entire sea bounded by known or inferred occurrences at the extremes. Local guides portray a smaller portion of the globe, and so can indicate ranges in strips along the coast, as Branch et al (2005) do, but the strips are continuous, and it is likely that members of most species occur in only some of the places indicated, occurrences dictated by the presence of appropriate habitat. Such abstractions over-represent the range of a species.

Maps indicating actual occurrences are typical in technical publications, such as Wallace (1999), and in the growing number of biodiversity websites such as that to sea anemones and relatives (Fautin 2008: eg Fig. 2). With few exceptions, it is likely that members of a species occur in more than the places indicated on the maps, which are where they have been observed or from which they have been collected. These concrete depictions under-represent the range of a species.

A solution

As has been known for many years (Allee et al. 1949), to a first approximation, an organism's range can be inferred from abstracting its habitat characteristics based on places the organism is known to occur, then assuming the organism occurs where its habitat does. Computerized methods make the four-step process of developing such range maps theoretically straightforward. 1) Occurrence records of a species and 2) maps depicting the distribution of relevant environmental parameters are overlain. 3) An algorithm abstracts the values of the environmental parameters that coincide with occurrence records, then 4) maps the occurrence of the environmental parameters within the values known to be compatible with the existence of the organism.

The distribution of these values of environmental parameters is a first-cut inference of the occurrence of habitat suitable for the species and thus the potential range of the species. Modeled environmental data for the past and future allow inferences to be made about historical biogeography and how ranges may shift with climate change.

Many models have been developed to carry out such computations, differing in assumptions and underlying algorithms. Some are referred to as "niche models" but few actually consider biological features other than by proxy with habitat. Sixteen such modeling programs were tested against one another

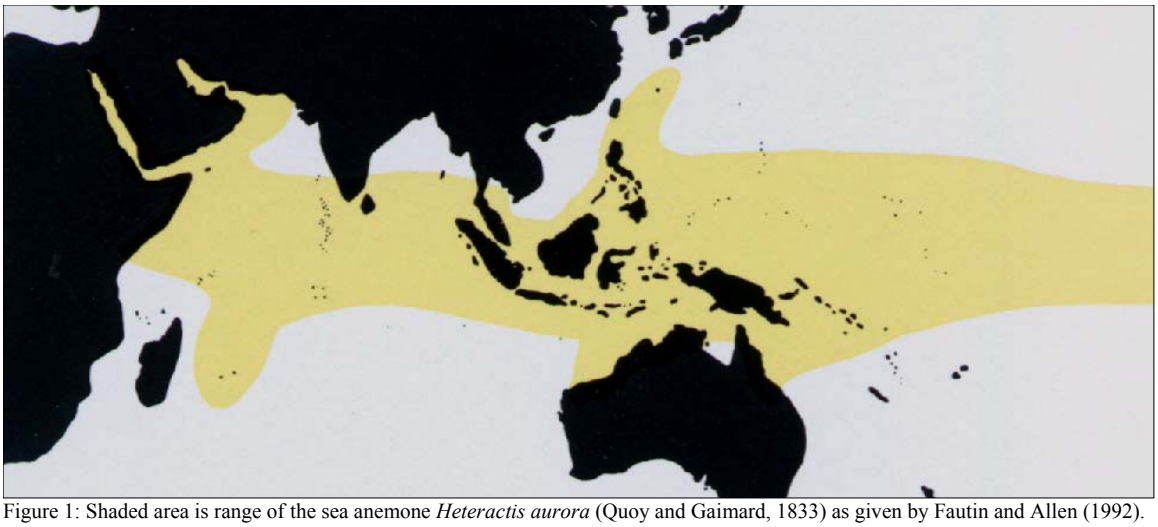

Figure 1: Shaded area is range of the sea anemone *Heteractis aurora* (Quoy and Gaimard, 1833) as given by Fautin and Allen (1992).

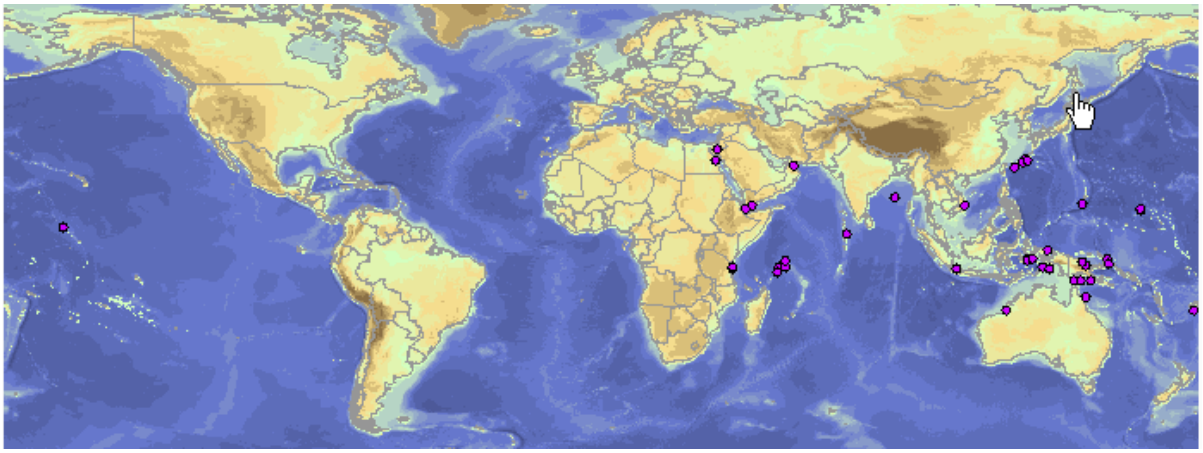

Figure 2: Published occurrences of the sea anemone *Heteractis aurora* (Quoy and Gaimard, 1833) as shown in Fautin (2008).

(Elith et al. 2006), but all were for terrestrial species. One of those programs had been used to model the distribution of some marine fishes, but did poorly for a variety of reasons (Wiley et a.l 2003).

Guinotte et al (2006) and Fautin and Buddemeier (2008) demonstrated the use of KGSMapper, a modeling program that handles marine data well. KGSMapper is associated with 42 spatially-explicit environmental parameters relevant to marine species. Grid size of the associated environmental data is half a degree -- coarse for some purposes – but the coverage is worldwide, which makes it appropriate for many uses. Further, KGSMapper is scale-independent, as demonstrated at "Scleractinian Corals and other Hexacorallians of the Northwestern Hawai'ian Islands" (http://hercules.kgs.ku.edu/hexacoral/hawaii/biodata) in which it is associated with finer-scale environmental data.

Some considerations

Presumably, precision of the environmental data and knowledge of a species' habitat requirements correlate directly with reliability of a range inference. Accuracy of the inference of a species' range should also increase with improved knowledge of the known distribution of the species. One way to maximize information of a species' occurrence is to include all records for the species regardless of the scientific name that was used for it.

Although ideally a single scientific name refers to a single species, many species have been given more than one name (such names are synonyms; International Commission of Zoological Nomenclature 1999). The sea anemone species for which the valid name is *Heteractis aurora* (Quoy and Gaimard, 1833) has been referred to in publication by 11 names (Fautin 2008): it was described as a new species three times, has been placed in nine genera, and has been misidentified.

The points on distribution maps in "Hexacorallians of the World" (Fautin 2008), which depict occurrence records from the published literature, are color-coded by the name used for the species. Because synonyms are a matter of taxonomy – they depend on a

scientist's opinion, and scientists may legitimately differ on whether two names (or more) refer to a single species – this convention allows a user to distinguish among the records by name, disregarding those that the user considers do not refer to the species in question. In fact, such a depiction can be informative in deciding whether a particular synonymy is justified.

Figure 3 is the KGSMapper output of suitable habitat for *Heteractis aurora* based on 75 occurrence records and the environmental parameters mean depth, mean and minimum surface seawater temperature, and maximum and minimum salinity. These parameters were selected because they are relevant to the biology of these anemones. The animals are zooxanthellate, so occur only in shallow water, and are confined to warm, fully saline seas. They are also known only from the Indo-Pacific. Within that natural range, the model output depicts the animal's potential range; this can be used to infer occurrence of members of the species in places where sampling has not been done, which can be useful, for example, in planning fieldwork, or inferring areas into which the animals might expand as climate changes. Outside that natural range (in the Caribbean, for example), the model output can be used to infer where the species might unnaturally occur, as, for example, where it might invade and persist. On the website "Hexacorallians of the World," the darker the reddish color, the more likely the habitat is to be suitable (see Guinotte et al. 2006).

Figure 4 depicts the habitat suitable for *Heteractis aurora* based on the same environmental parameters as for Figure 3, but uses only those occurrence records that referred to the species by one of its synonyms, *Radianthus koseirensis*. Presumably both the smaller number of records and the restriction of them to the western portion of the species' range leads to the conclusion that the species is likely to be

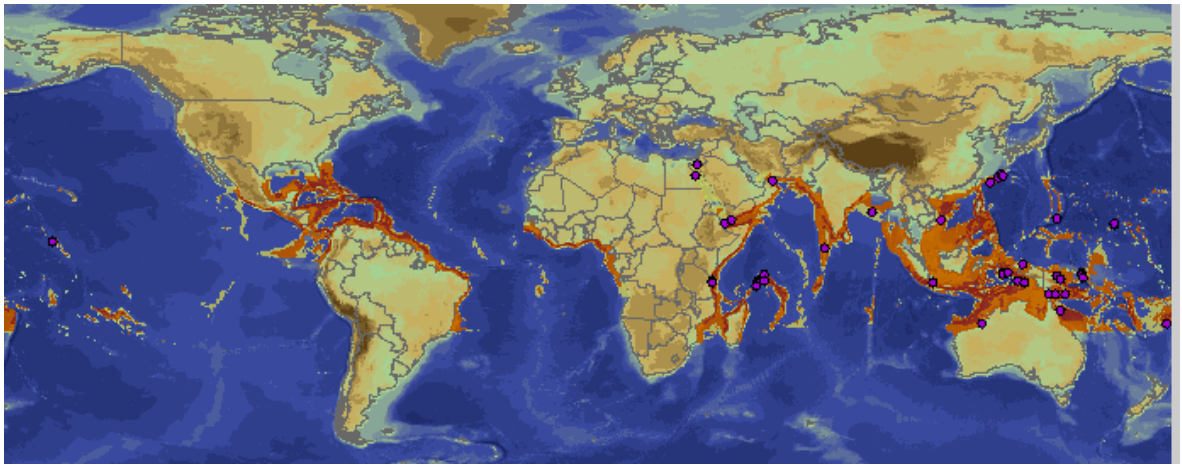

Figure 3: Suitable habitat for *Heteractis aurora* (Quoy and Gaimard 1833) inferred by KGSMapper from 75 published occurrence records (closed circles), and the environmental parameters mean depth, mean and minimum surface seawater temperature, and maximum and minimum monthly salinity. The darker (the reddish color), the more likely the habitat is to be suitable (Guinotte et al. 2006).

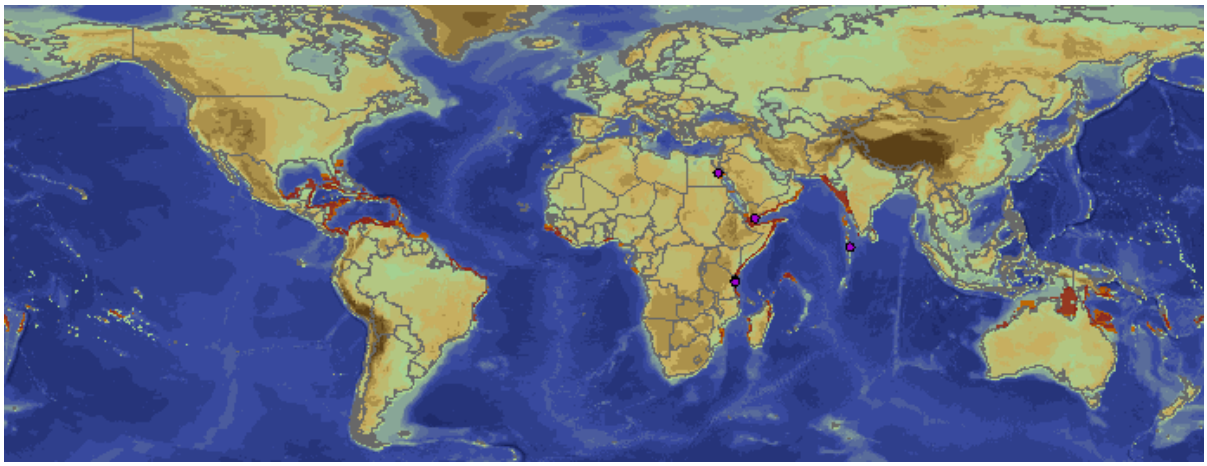

Figure 4: Suitable habitat for *Heteractis aurora* (Quoy and Gaimard 1833) inferred by KGSMapper only from published occurrence records (closed circles) that used the synonymous name *Radianthus koseirensis*. The darker (the reddish color), the more likely the habitat is to be suitable (Guinotte et al. 2006).

far less widespread than is seen in Figure 3. When rendered in black and white, the difference in model output is easiest to perceive in Southeast Asia, where the shaded area of inferred occurrence is more widespread and darker in Figure 3 than Figure 4.

Plotting occurrences using a species name rather than a species concept (by including synonyms) can be not only incomplete but may be misleading. That is because more than one species may have been given the same scientific name (such names are termed homonyms; International Commission of Zoological Nomenclature 1999). Homonyms are not a matter of opinion, but are objectively verifiable, and thus fall within the province of nomenclature. The anemone species to which the name *Heteractis aurora* properly belongs occurs strictly in tropical waters of the Indo-Pacific. That species was first placed in the genus *Actinia* (to which nearly all sea anemones were initially assigned). What is clearly a different species in Britain was also given the name *Actinia aurora*. Applying a model to infer distribution from records that include occurrences of the British species would obviously give a meaningless result.

Conclusions

Use of modeling programs to infer the range of a species from known occurrences and features of the environment benefits from

- accurate and precise knowledge of the species' habitat and natural history (to select environmental parameters relevant to the organism's life that control its distribution)
- knowledge of biogeography (where the organism would be expected to occur, so invasions can be distinguished from occurrences in places where the species might be expected but has not previously been recorded)
- consideration of taxonomy and nomenclature (what other names have been applied to it – and which applications of a name do not refer to the species in question)

Diversity and abundance of reef macro invertebrates (Mollusca; Echinodermata) in the southern Gulf of California, México

M. D. Herrero-Pérezrul

Centro Interdisciplinario de Ciencias Marinas. Instituto Politécnico Nacional. Ave. Instituto Politécnico Nacional s/n
Col. Playa Palo de Santa Rita. C. P. 23096 La Paz, B.C.S., México. dherrero@ipn.mx

Abstract. Diversity and abundance of macro mollusks and echinoderms were estimated on three protected islands in the southern Gulf of California. From February 2005 to February 2007, each island was visited twice during warm and cold season. These estimates were calculated from a total of 165 belt transects (25 x 2 m). 22 species of echinoderms and 23 of mollusks were identified. Species richness and abundance showed statistical differences among the islands for both phyla; however, diversity did not. Species assemblages were different on each island. Espíritu Santo had more echinoderms and San José had more mollusks. Asteroids were the most abundant, followed by echinoids and holothurians. The dominant species were the sea star *Phataria unifascialis*, followed by the sea urchin *Tripneustes depressus* and the holothurian *Holothuria fuscoscinerea*. Gastropods were the most abundant with 12 species, whilst bivalves had 7. San José and Cerralvo had more gastropods species than Espíritu Santo. The dominant gastropod and bivalve were *Serpulorbis margaritaceus* and *Pinctada mazatlanica* respectively. The echinoderm and mollusk fauna are similar on the three islands, the community structure is stable along the study area; it seems that habitat type has a strong influence on the distribution and abundance of both phyla.

Key words: Echinoderms, Mollusks, Gulf of California, Abundance, Diversity.

Introduction

The Gulf of California, México, is one of the most important areas for reef species conservation worldwide (Roberts et al. 2002). In the Gulf, the NPA "Islas del Golfo de California" comprises more than 100 islands (Anonymous 1986; 2000a). Many of them support artisanal fisheries and tourism activities thus representing an important economic resource. The islands from the southern Gulf (San José, Espíritu Santo and Cerralvo) are characterized mainly by rocky bottoms which support the presence of isolated coral patches and coral communities, particularly in shallow waters around the islands (1-10 m depth). In this area, coral cover is usually less than 10% (Reyes Bonilla et al. 2005a).

Macro invertebrates, especially mollusks and echinoderms (Asteroidea, Echinoidea, Holothuroidea, Gastropoda, Bivalvia, Opistobranchia) are commonly associated to these communities (Keen 1971; Brusca 1980; Maluf 1988; Cintra Buenrostro 2001; Skoglund 2001; 2002; Solís Marín et al. 2005) and some of them are subjected to local fisheries and some are protected by law (Anonymous 1994). Both phyla play an important ecological role interacting actively with other species and therefore influencing benthic community structure (Benedetti-Cecchi 2001; Chapman 2002). Species assemblages depend greatly on resource availability and on the distance to other populations (Hansky 1991; Woodward & Kelly 2002). However, little is known about the patterns of species assemblages. Even though the mollusk and echinoderm fauna is well known in the Gulf of California (Verrill 1870; Ludwig 1893; Holguín Quiñones et al. 2000; Reyes Bonilla et al. 2005b; González Medina et al. 2006; Herrero-Pérezrul et al. 2008), only a few studies have been directed to ecological aspects of these macro invertebrates. The objective of this study was to analyze the community structure of Mollusk and Echinoderms from San José, Espíritu Santo and Cerralvo discussing some ecological aspects such as abundance, dominance, species richness and diversity.

Material and methods

The islands San José (SJI), Espíritu Santo (ESI) and Cerralvo (CRI) (Fig. 1) were visited twice from February 2005 to February 2007, considering two seasons, warm (Jun-Nov) and cold (Dec-May). A total of 165 (25 x 2 m) belt transects were used to assess the macro invertebrate community on the three islands. Community structure was monitored through the estimation of abundance and frequently used

ecological indexes (Magurran 2004). We calculated the Shannon-Weaner's diversity index (H´), which considers the proportion of the abundance and species richness from the sample and was calculated with the formula:

$$H' = -\Sigma (p_i) (\log_{10} p_i) \quad (1)$$

where: H' = data from the sample in bits/individual; s=species number; p_i = proportion of the total sample in the i-th species.

Data were tested for homoscedasticity using a Kolmogorov-Smirnoff test. A one way ANOVA (α=0.05) was used to compare differences amongst the island's index and used a Tukey test to detect the origin of differences (Zar 1999).

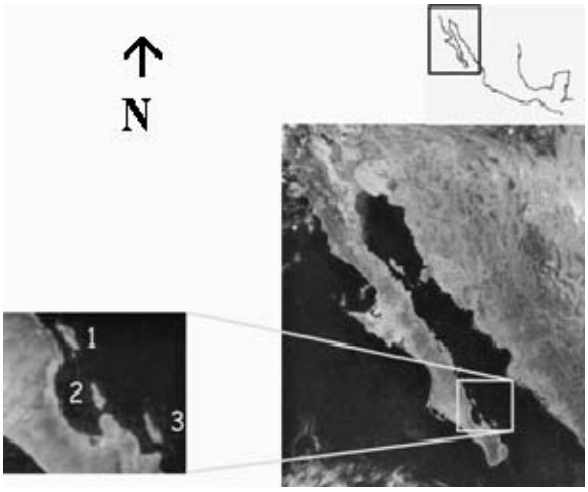

Figure 1. Study area. **1**. San José is located at 25°6'N, 110°31'W; **2**. Espíritu Santo at 24° 4'N, 110°27'W; **3**. Cerralvo at 24°8'N, 109°47'W.

Results

During this study, we counted a total of 5310 echinoderms belonging to 23 species (12 asteroids, 7 echinoids and 4 holothurians) (Table 1); and a total of 2264 mollusks belonging to 22 species (9 gastropods, 7 bivalves and 6 opistobranchs) (Table 2). Species richness of echinoderms and mollusks was not statistically different amongst the islands ($F_{2,26}$= 2.4397, P = 0.09084 and $F_{2,26}$ =1.0643; P =0.36136, respectively). Despite the similarity in richness, the species assemblages were different on each island.

The Class Asteroidea was the best represented on the island complex, followed by Echinoidea and Holothuroidea. The abundance of echinoderms showed statistical differences between the islands ($F_{2,26}$=4.0437, P=0.02958). The Tukey test detected that ESI had the highest values with more than 2500 individuals belonging to the three classes, followed by SJI with almost 2000 individuals, and CRI with less than 1000. At class level, Asteroid abundances also showed statistical differences between the islands ($F_{2,26}$=8.8096, P=0.0012), but holothurians did not ($F_{2,26}$=2.7287, P=0.0942).

The most abundant species was the sea star *Phataria unifascialis,* found ubiquitously along the three islands, followed by the sea urchin *Tripneustes depressus* and the sea cucumber *Holothuria fuscoscinerea*. The commercial holothurian *Isostichopus fuscus* had the lowest abundance (0.07 $\pm$ 0.006 ind/m^2).

Table 1. List of Echinoderm species. * Species observed at the study site but not counted.

Asteroidea	Echinoidea	Holothuroidea
Achanthaster planci	*Arbacia incisa*	*Euapta godeffroyi*
Asteropsis carinifera *	*Centrostephanus coronatus*	*Holothuria fuscoscinerea*
Astrometis sertulifera *	*Diadema mexicanum*	*Holoturia kefersteiini*
Echinaster tenuispina *	*Echinometra vanbrunti*	*Isostichopus fuscus*
Heliaster kubiniji	*Eucidaris thouarsii*	
Linckia columbiae	*Toxopneustes roseus*	
Linckia guildingui *	*Tripneustes depressus*	
Mithrodia bradleyi		
Nidorellia armata		
Pentaceraster occidentalis		
Pharia pyramidatus		
Phataria unifascialis		

Table 2. List of Mollusks species. * Species observed at the study site but not counted.

Bivalvia	Gastropoda	Opistobranchia
*Chama frondosa**	*Cerithium uncinatum**	*Elyisia diomedea*
Hyotissa hyotis	*Chromodoris norrisi*	*Glossodoris sedna*
Nodipecten subnodosus	*Conus sp.*	*Hypselodoris ghiselini*
Pina rugosa	*Murex tricoronis* *	*Navanax aenigmaticus*
Pinctada mazatlanica	*Muricanthus princeps*	*Tambja abdere*
Pteria sterna	*Plicopurpura patula pansa*	*Tambja eliora*
Spondylus calcifer	*Serpulorbis margaritaceus*	
	Strombus galeatus *	
	Thyca callista *	

Regarding mollusks, the community analysis showed that gastropods were the most abundant, followed by bivalves and opistobranchs. The species richness of gastropods showed statistical differences amongst the islands ($F_{2,26}$= 6.8816; P = 0.00503), with the highest value at SJI and the lowest at ESI (Fig. 2). Bivalves were slightly more abundant at ESI and less at CRI, however, no statistical differences were detected ($F_{2,26}$=1.0643; P =0.36136).

The most abundant mollusk was the gastropod *Serpulorbis margaritaceus*, followed by *Muricanthus princeps*. It is important to emphasize the common presence of the mother of pearl *Pinctada mazatlanica*, which amongst the bivalves showed the highest density (0.052 ± 0.03 ind/m^2).

Echinoderms were more diverse than mollusks, but no statistical differences were observed on diversity estimates amongst the islands for both phyla ($F_{2,26}$=2.04, P= 0.3597 and $F_{2,26}$=3.2614, p=0.05448 respectively) (Fig. 3).

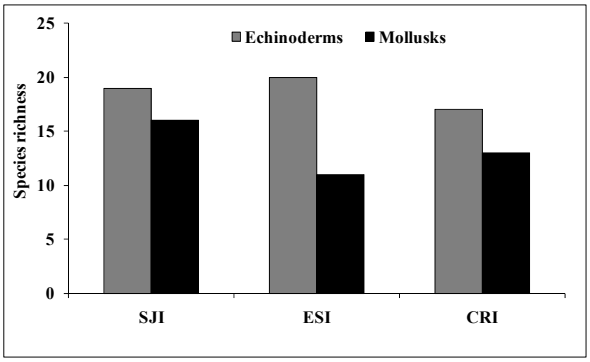

Figure 2. Species richness amongst islands.

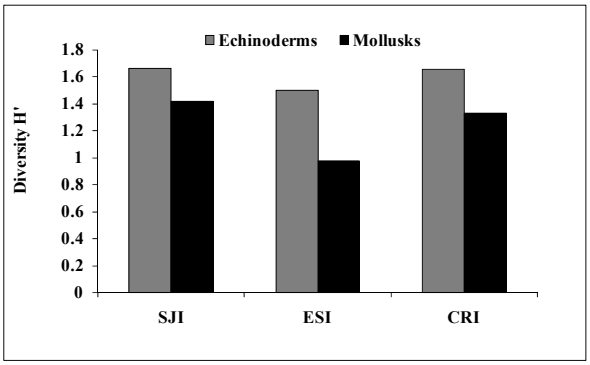

Figure 3. Diversity of echinoderms and mollusks amongst islands.

Species assemblages of echinoderms were different on each island, except for asteroids. The echinoid *Tripneustes depressus* was more abundant in SJI, whilst in ESI was *Eucidaris thouarsii* and in CRI was *Toxopneustes roseus*. Regarding holothurians, *Holothuria fuscoscinerea* was the most abundant and was commonly observed on the three islands, however, *Euapta godeffroyi* was more abundant in ESI and *Isostichopus fuscus* in CRI. Except for the gastropod *Serpulorbis margaritaceus,* the same behavior was observed for mollusks. Gastropods were similarly abundant on the three islands, but bivalves were more abundant in ESI and opistobranchs in SJI. The bivalve *Pinctada mazatlanica* and the gastropod *Muricanthus princeps* were more common at ESI. The images of the dominant species are depicted in (Fig. 4). The holothurian *Isostichopus fuscus* is also shown because of its protection *status* and high importance as an economic resource.

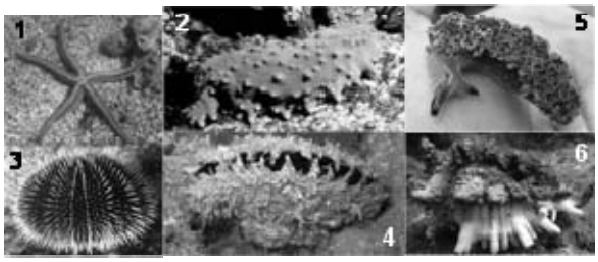

Figure 4. Dominant species at the study site. 1 *Phataria unifascialis*; 2 *Isostichopus fuscus*; 3 *Tripneustes depressus*; 4 *Pinctada mazatlanica*; 5 *Elysia diomedea*; 6 *Muricanthus princeps*.

Discussion

Field visual observations corroborated the number of species of macro mollusks and echinoderms found by census. Since the insular complex involved rocky bottoms, it is possible that some species might have been overlooked due to their habits. Particularly echinoderms were commonly observed hidden in crevices, small caves and between coral branches. Similarly, the gastropod *Serpulorbis margaritaceus* was abundant and frequently counted between coral branches of *Pocillopora* spp. Coral communities and patches from the study area are dominated by *P. verrucosa* and *Porites panamensis* (Gastil et al. 1983; Reyes Bonilla et al. 2005a), and the important role of corals as refuge and substrate for many invertebrates is well known (James 2000, 2006).

The number of macro-echinoderm species varies along the Gulf of California, increasing towards tropical latitudes (Maluf 1988; Cintra Buenrostro 2001), however, it seems that the community structure of echinoderms in the Gulf is relatively homogeneous and is dominated by asteroids (Reyes Bonilla et al. 2005b; Herrero-Pérezrul et al. 2008). At the study site, echinoderms were more abundant and diverse than mollusks. For both phyla, despite the fact that diversity showed no statistical differences among the islands, the species assemblage was different. This is probably related to habitat type. ESI is characterized by a number of shallow bays favoring coral communities and species associated to them. On the other hand SJI and CRI bottoms are mainly composed by boulders and coral communities are less abundant (Reyes Bonilla et al. 2005a).

Regarding echinoderms, asteroids showed the highest value of species richness. It is important to mention that *Phataria unifascialis* was the dominant species, the high values could explain the statistical differences amongst the islands. Some authors consider this sea star as herbivorous (Reyes Bonilla et al. 2005b). During early 1980's the dominant sea star in the Gulf of California was *Heliaster kubiniji*, a

carnivorous sea star, however, in subsequent years, its populations decreased drastically, probably due to the effects of ENSO 1983 or maybe a pathogen (Dungan et al. 1982). *H. solaris* decreased its abundance in the Galápagos Islands after the 1983 ENSO (Hickman 1998). To this date *H. kubiniji* shows no sign of recovery, and it is now considered as rare due to its low densities (Herrero-Pérezrul et al. 2008). It possible that this species shift from carnivorous to omnivorous had some effects on the community structure, however, there is not enough data to support or reject this argument.

On the other hand, we have the presence of *Acanthaster planci*, a well known coral predator. This asteroid had low densities (0.022 ± 0.0016 ind/m^2), it is interesting to notice that it was more commonly observed on rocky bottoms feeding on bryozoans and octocorals. This is easily explained by the fact that in the study area, coral cover is very low (Reyes Bonilla et al. 2005a), thus, there is not enough coral to feed on and it must feed on what is available.

Other important echinoderm is the holothurian *I. fuscus*, which is currently under especial protection by the Mexican government (Anonymous 2000b). The low abundances found in the study site may be caused by legal fishing activity, however, it is possible that these values were also influenced by small (but constant) levels of illegal fishing.

Regarding mollusks, the relatively high abundance of the mother of pearl *P. mazatlanica* is worthwhile to mention. This bivalve was considered an endangered species since early 20th century, and even though data on abundance of wild populations are old and scarce, there is some evidence of an increase on density population (González Medina et al. 2006), and in this study density was even higher that that reported by the authors. It seems that the protection has served its purpose.

One of the most curious mollusk found in this study was the gastropod *Thyca callista*, which parasites *P. unifascialis*. It was not counted on the census, because is mostly hidden on the oral surface of the sea star and is not visible. However, it seems that its presence is common in the Gulf of California (Salazar and Reyes Bonilla 1998, Herrera Escalante 2005). This could be explained by the fact that *P. unifascialis* is more abundant in the Gulf than in the rest of the Pacific coasts of México.

In conclusion, the echinoderm and mollusk fauna are similar on the three islands. The community structure is stable along the study area; it seems that habitat type has a strong influence on the distribution and abundance of both phyla.

What are the costs of bad taxonomic practices: and what is *Madracis mirabilis*?

J.M. Locke[1], K.A. Coates[2]

2) Min. of Environ. and Sport, Dept. of Cons. Serv., 12 North Shore Road, Flatts, FL 14, Bermuda

Abstract. The variety of information available today for identification of biological species should allow repeatable and verifiable recognition of the same species by many investigators. However, if good taxonomic practices are not employed, this is not the case. The cost of producing data, which cannot be referred to a described species, is explored here for studies that cite the names *Madracis mirabilis* (Duchassaing and Michelotti 1860) or "Madracis mirabilis sensu Wells 1973". We estimate that in half of such studies published since 1967, specimens named as *M. mirabilis* are not referable to any single species. As such, data from these studies cannot be applied in any analyses that have species-level implications – including studies of diversity, physiology, reproduction, biogeography, ecology and evolution. A rough estimate of the dollar costs of producing these compromised data is just under $4 million dollars. A few basic steps toward improved taxonomic procedures are 1) reference to original materials, including type specimens, original descriptions and study-specific reference materials; 2) a working knowledge and understanding of the international code of zoological nomenclature; 3) maintenance of reference specimens and of records of identification methods and observations; and 4) documenting identification methods within publications.

Keywords: *Madracis auretenra*, *Madracis myriaster*, *Madracis mirabilis*, type specimens, taxonomic code

Introduction

The recent description of a new, but commonly encountered, Caribbean scleractinian coral species, *Madracis auretenra* (Locke, Weil and Coates 2007), raises, again, the high costs of embedded, poor, taxonomic practices. For about 40 years this species has been regularly misnamed as *Madracis mirabilis* (Duchassaing and Michelotti 1860). Mistakes in identification happen, but the errors in evidence here result mostly from using poor taxonomic procedures and represent an unjustifiable waste of expensive, limited, resources. Undertaking only a few, simple procedures would almost guarantee better taxonomy.

For many years *M. auretenra* has been misnamed as *M. mirabilis*. Subsequent to a comprehensive revision by Cairns (1979) of deep-water scleractinians of the Caribbean, some authors named their specimens as "M. mirabilis sensu Wells 1973" (Wells 1973), which Cairns clearly indicated was not the same species as *M. mirabilis* (Duchassaing and Michelotti 1860). *M. auretenra* is shown in Fig. 1. It is a shallower water species, which has zooxanthellae; and it has the apt common name, yellow-pencil coral.

Madracis mirabilis, shown in Fig. 2 is a subjective junior synonym for *Madracis myriaster* (Milne-Edwards and Haime 1849) and *M. myriaster* is a Western Atlantic, deep-water species that does not have zooxanthellae. Type material of *M. mirabilis*

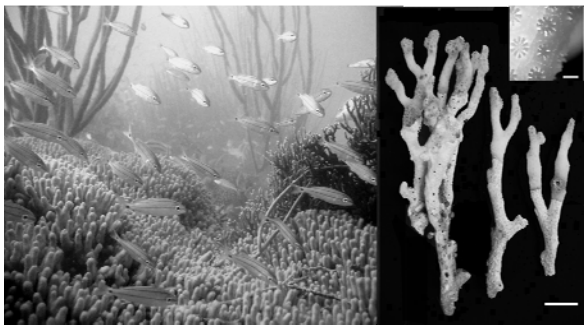

Figure 1: *Madracis auretenra* at Shelly Bay Shoal, Bermuda (left) and holotype (right), from Media Luna SW, Puerto Rico (scale 2 cm), with a close up of the spiny coenosteum (scale 1 mm) (Locke et al. 2007; reproduced courtesy of the Proceedings of the Biological Society of Washington). This species has been misnamed *M. mirabilis* for many years.

and in vivo specimens of *M. myriaster* are shown in Fig. 2. A thoroughly researched synonymy for *M. myriaster* up to 1979 is provided by Cairns (1979); a number of other authors, both before Cairns and more recently, recognized the morphological identity of *M. mirabilis* to *M. myriaster*.

In this paper we present the results of our attempts to discover the identity of specimens that have been named as *M. mirabilis* or as "M. mirabilis sensu Wells" in papers published since 1967. In particular we wanted to know whether these specimens were or were not *M. auretenra*. We also made a rough

estimate of a dollar value for the research effort that might be considered wasted, if no species identity can be resolved. Finally, four simple procedures toward better standards and outcomes of taxonomic practices are provided.

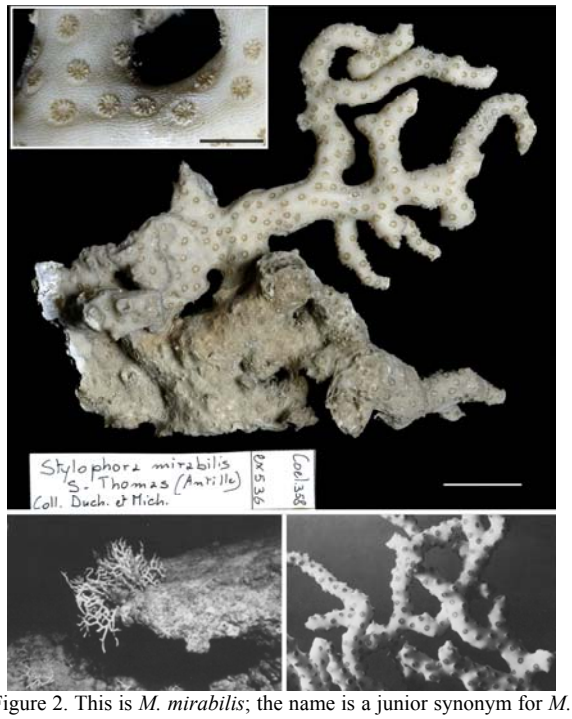

Figure 2. This is *M. mirabilis*; the name is a junior synonym for *M. myriaster*. Type material of *M. mirabilis* from the Zoological Museum of Turin (top) (scale 2 cm). The inset provides a close up of the striate coenosteum (scale 1 cm). Living material of *M. myriaster* from 196 m depth, Castle Roads, Bermuda (Fricke and Meischner 1985).

Methods

Computerized literature searches and visual searches of literature cited sections of relevant publications were made to locate primary references published since 1969 using the species name *M. mirabilis* (Table 1). The first or principal authors of the publications were contacted by electronic mail to see whether they could confirm the identity of their study material as *M. auretenra*, *M. myriaster* or another species, by looking for the distinguishing morphological features that became apparent once *M. auretenra* had been described (Locke et al. 2007). Authors were also asked the source of their current information about their specimens: memory, photographs, reference specimens, or another source.

To estimate a tangible cost of data that are unusable due to incorrect and unrecoverable identifications, we considered the dollar value of time and other resources we have spent describing *M. auretenra*, disseminating that information, and trying to resolve which earlier studies were relevant to *M. auretenra* (Table 2). Then we applied this value to the studies that produced such data. In particular, data that could not be cited in a review of the biology of the new, but very well-studied species, *M. auretenra*, were considered unusable.

Results

The cumulative results of literature searches, queries and responses are shown in Table 1.

Table 1. Use of *Madracis mirabilis* or "M. mirabilis (sensu Wells 1973)" since 1967

Number* of PUBLICATIONS (type 1) naming *M. mirabilis* as a study species (*does not include many regional species lists)	146
PUBLICATIONS (type 2) since July 2007 (post publication of *M. auretenra*) naming *M. mirabilis* (in journals: Coral Reefs, Molecular Ecology Notes, Marine Biotechnology, Marine Biology; and in Coral Reefs of the USA)	6+
Presentations at ICRS 11 naming *M. mirabilis*	**3+**
Number of different first authors of the PUBLICATIONS (type 1, only)	88
Number of investigators to whom *M. auretenra* paper (Locke et al 2007) was distributed (includes some secondary authors)	60
Number of PUBLICATIONS (type 1, only) for which species identities have been verified as *M. auretenra*	60 (41.1%)
Number of PUBLICATIONS (type 1, only) not verified (1. no reply from authors [46 authors], 2. authors could not verify identity [2 authors], or 3. no current contact information for authors [38 publications])	86 (58.9%)
Validation resources reported by responding authors: Reference specimens; Photographs of specimens; Written details of specimens; Personal recollection of specimen details; Field site revisited	

The number of publications naming *M. mirabilis* that we have found, so far, for the period 1967 to July 2007 is 146. More than ten have been published since 2007, including in some prominent publications (such as the journal Coral Reefs, in the new volume "Coral Reefs of the USA" [Riegl and Dodge 2008]), and in the 11th International Coral Reef Symposium abstracts. The 60 publications for which a species identity could be verified included many in which substantial taxonomic information was included, such as close-up photographs of the corallites and coenosteum or detailed descriptions of those structures, or some clear indication by the author(s) that they were not studying *M. mirabilis* (= *M. myriaster*). Eighty-six of the published studies (Table 1) remain doubtful with regard to a species identity. There were three primary reasons why the identity of the specimens could not be or were not verified by the authors of the papers (in descending order of numbers of incidences): no current contact information for the

authors; no response from authors (perhaps because the contact information found was not current); and the authors had no materials or detailed recollections from which they could verify the identity of their specimens.

We prompted authors to indicate the category of resource that they used to verify their morphological species identifications and found that they were mostly as we had expected - reference specimens, good quality photographs, personal, unpublished, descriptions of material, and other personal recollections; however, some authors were also able to revisit their study sites and make new observations of the specimens.

Our evaluation of the time we committed to our studies is shown in Table 2. This is based on actual costs, salaries and in-kind contributions to the project; overhead was both charged against some of the funding for this project and provided as an in-kind contribution, but it is all indicated as overhead.

Table 2. Cost estimate for the *M. auretenra* research project

Expense category		Value USD
Direct costs	Student stipend @ 21,0000/yr*3yr	63,000

Total costs		138,510

Our expenses related to the publication of the new species *M. auretenra* and to our attempts to widely disseminate information and to affect a correction to the ongoing misidentification of *M. mirabilis* were near $140,000 USD.

Discussion

Data, derived from specimens for which a morphological identity cannot be confirmed, cannot be used in comparative analyses with species-level implications – including studies of: reef ecology, coral physiology, biochemistry, palaeobiology, environmental degradation and global climate change (see Winston 1999 for specific examples). Even if species identity ('getting the name right') is not essential to developing an hypothesis, it still can be very significant whether data from a single species or from a conflated taxon is considered (Weil and Knowlton 1994; Winston 1999). In the case of "M. mirabilis sensu Wells" no description existed for the misnamed "species" prior to 2007 so that authors had very little to refer to as far as producing a consistent identification among different studies. Therefore, it would be hard to justify any assumption that all authors were working on the same, and just one, morphological species.

We know that data from 86 studies, which might be relevant to *M. auretenra*, cannot be included in a review of the biology of that well-studied, widespread, and common species; in fact, at this point those data could not be included in such a study of any coral species. However, the same data may be applicable to very general questions about coral reef ecology and biology. Thus, conservatively, we suggest that only a third of the data produced in those studies has extremely limited value. If we consider that the cost of our studies is in a similar range to the studies we cited and apply a current cost to research over the whole period of the publications we consider, then we would be looking at a total expenditure of about $3,970,620 for data with limited to no value.

This is equivalent to about 57 years of salary for one taxonomic research scientist, with an averaged income through their career of $70,000 per year. This is more than one entire career or equivalent to 30 years salary, a relatively long career, accompanied by an annual research budget of $62,000.

Employing poor taxonomic practices is having significant, long-term, negative impacts on the entire field of coral reef research; both through the negation of data and hypotheses that are used to justify research and conservation protocols and through, simply, wasting large amounts of time and money.

We recommend four easy steps towards better taxonomy, which have been noted in a number of publications on taxonomic procedures, for example, see Winston (1999).

1. Establishing identity:
   - consult original descriptions – electronic copies of original materials are readily provided by most institutions
   - consult with taxonomic experts - question and understand their identification criteria
   - consult type material - types for many Caribbean corals are deposited at the Smithsonian, or other major reference museums in the United States, such as the Peabody at Yale, and at major European museums; they often will lend material or will send good quality images free of charge
2. Understanding naming practices – consult the International Code of Zoological Nomenclature. It is available online at: http://www.iczn.org/iczn/index.jsp
3. Maintaining reference materials

4. Documenting identification methods – record primary and secondary references, comparative methods (material examined), and authorities consulted

The kinds of data available for the identification of scleractinian corals go well beyond the structural features that were the original basis of distinguishing many species. However, no matter what kind or how many data are applied to the question of taxonomic identity, if good taxonomic practices are not applied then good results are not expected.

A review of the biology of the very well-studied coral *M. auretenra* is in preparation. If you have participated in or know of a study that is relevant, please contact J.M. Locke at <janmlocke@yahoo.com>.

Abstract. Cryptofauna associated with colonies of dead coral is important due to their role as bioeroding organisms that alter the physical structure of reefs. We studied dead colonies of *Montastraea annularis* to obtain information on the main groups present and their relative abundance at Los Roques Archipelago National Park (reefs of Dos Mosquises, Cayo La Pelona, and Cayo Sal). Dead corals were collected at 6-8 m and 9-13 m depth, (3 fragments at each location), and colony volume was estimated for density values standardization. Fragments were broken down in the laboratory and organisms were separated. In all, 1,499 individuals in 8 taxonomic groups were found. The most abundant were sipunculids (57.29%), followed by polychaetes (20.45%), crustaceans (14.76%), nematods, mollusks, and echinoderms. The fauna associated with reefs fragments is highly diverse, but consistently dominated by the same groups.

Key words: cryptofauna, *Montastraea annularis,* dead colonies

Introduction

Coral cryptofauna, initially defined by Klumpp et al. (1988) as mobile organisms using spaces available in coral rock, is made up mainly by a large number of invertebrates. This community of organisms, associated with the reef's calcareous skeleton, inhabits cracks and holes and is classified into borers and opportunists. Borers make cavities in the calcareous layer thus increasing the surface for colonization by organisms such as sponges, bivalves, crustaceans, sipunculans and polychaeta (Hutchings 1974, 1992). Opportunists are unable to bore but take advantage of cavities created by borers. Here one must also include fauna inhabiting the outer surface of the coral, such as fish, crustaceans, echinoderms, and algae. Cryptofauna is has been demonstrated to contribute to the breakdown of the carbonate reef structure in the long run. Few studies in the Caribbean deal with the biodiversity of cryptofauna and none at all concern the southern Caribbean (Ochoa-Rivera et al. 2000; Campos-Vasquez et al. 1999; Moreno-Forego et al. 1998).

The objectives of the present study were to study the biodiversity of crypto fauna associated with dead fragments of *Montastraea annularis*, the dominant species in the region (CARICOMP 1991, Bone et al. 2001), and to evaluate the spatial variations in the distribution of these organisms between various locations on the reef and at different depths.

Material and Methods

This study was executed at Los Roqués Archipelago, (11º 44´45″ - 11º 58´ 36″ N., and 66º 32´ 42″ - 66º 52´ 57″ W; Weil 2003).

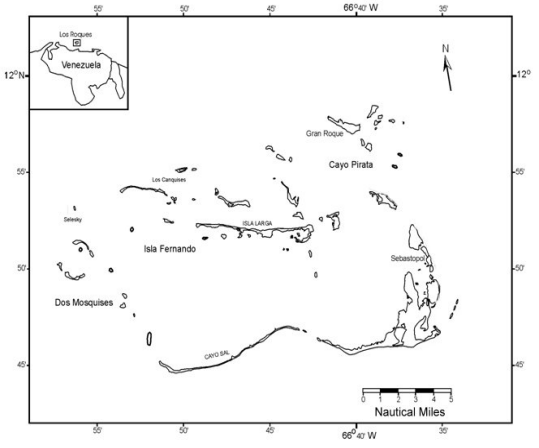

Figure l. Map of Los Roques Archipelago National Park indicating Cayo La Pelona (1), Dos Mosquises Sur (2), and Cayo Sal (3) (Modified from Villamizar et al. 2003). (Fig.1) at two depths (6-8 m and 9-14 m).

Dead fragments *of M. annularis* the second most important coral species in these reefs (14% of total cover; Villamizar et al. 2003) were used. The samples (3 fragments or pillars of *M. annularis*) were taken at Dos Mosquises, Cayo La Pelona, and Cayo Sal. The most exponed and deteriorated pillars were

taken, bringing the total to 18 samples. In the laboratory, coral fragments were broken into smaller pieces with chisel and hammer and organisms were extracted and separated in broad taxonomic groups. Results from the different locations and depths were compared by Kruskal-Wallis analyses ($p<0.05$).

Results

A total of 1.499 individuals were collected, belonging to 8 taxonomic groups, with a mean density of 116±132 ind/l. Sipunculans were dominant, with a relative abundance of 57.3% (mean density of 66±97 ind/l) followed by polychaetes 20.45% (24± 29 ind/l) and crustaceans 14.76% (17±18 ind/l). Chitons, echinoderms, bivalves, gastropods and nematods were also found, but their relative densities was always less than 5% (Table I). The greatest mean density of cryptofauna was found at Dos Mosquises, with 165±216 ind/l, followed by Pelona (131±55 ind/l) and Cayo Sal (51±39 ind/l). Sipunculans always dominated (55.9%, 60.6% and 53.4%), polychaetes were the second most important group in Dos Mosquises and Cayo Sal, with 21.7% and 35.3% respectively. In Pelona, crustaceans (15.6%) were the second group and polychaetes the third, representing 13.09% of the total.

	DMS		PELONA		CAYO SAL		TOTAL	
Invertebrate groups	S	D	S	D	S	D	S	D
Sipunculids	164	21	106	54	28	27	99	34

Total	262	69	153	110	44	57	153	79
Total/groups	7	7	8	7	4	6	8	8

Table 1:. Mean density for the invertebrate groups of the cryptofauna for the 3 reef locations (S= shallow, D= deep).

No significant differences were found among the three locations. The shallower zone showed higher density (153±176 ind/l vs. 78±55 ind/l). Sipunculids were more abundant in the shallower zones of all reefs (K-W p: 0.019, Table 1), whereas both groups were dominant in deeper zones.

Discussion

Except for the fact that sipunculids and polychaetes were the dominant cryptofauna at all reefs and all depths, no spatial patterns were noticeable in the distribution, composition, and abundance of cryptofauna. Other studies have also found sipunculids more abundant in the shallower zone (Perry 1998), which could be related to greater biomass, cover and complexity of algae that provide food, substrate and protection (Klumpp et al. 1988), or sipunculid distribution patterns may be more directly related to the degree of dead coral and reef degradation (Peyrot-Clausade and Brunel 1990; Capa 2003; Fonseca et al. 2005). Campos-Vasquez et al. (1999) and Ochoa-Rivera et al. (2000) reported greater polychaete density in the shallow zones of reefs located in Punta Nizuc and Cozumel and explained it by anthropogenic reef degradation. Thus, the lower polychaete densities at Los Roques may indicate good reef health there. Dead coral cover between 14 and 20% reached the maximum values in the shallow zone of La Pelona, where densities of sipunculids were high (Villamizar et al. 2003).

Densities of cryptofauna in this study are low compared to Moreno-Forero et al. (1998), who reported 328 ind/l for polychaetes and 213 ind/l for sipunculids in *Acropora palmata* samples from Colombia. These high values could be related to the state of degradation of the reefs at Isla Grande (Colombia), with <0.2% coral cover. Nonetheless, significant negative correlations were found between cryptofauna density and volume of coral fragments ($r=-0.54$ $p=0.02$), and between sipunculid density and fragment volume ($r=-0.52$ $p=0.029$). Thus more cryptofauna was found in smaller fragments. At Los Roques, high biodiversity of cryptofauna coincided with low abundante and an absence of spatial pattern. Cayo Sal exhibited the lowest diversity.

Studies of cryptofauna thus have the potential of acting as a useful indicador of reef health.

Acknowledgement

The authors wish to thanks Dra. Estrella Villamizar (Univ. Central de Venezuela), Fundación Científica Los Roques y Conservation International (CI), for providing all the logistics and financial support needed to conduct this project, and for allowing us to extract Monstastraea annularis fragments used to study the cryptofauna.

Abstract. We compared the Caribbean reef sponge, *Axinella corrugata,* with the Caribbean reef coral, *Erythropodium caribaeorum* for differences in their resident microbial communities. This cursory survey of bacterial diversity applied 16S rRNA gene sequences. Over 100 culture-independent sequences were generated from five different *Axinella* 16S rRNA libraries, and compared with 69 cultured isolates. The culture-independent 16S rDNA clones displayed a higher diversity of Proteobacteria, including "uncultured" or "unknown" representatives from the Deltaproteobacteria. *Arcobacterium*, and Cyanobacteria were also found. We have also confirmed that *Axinella* sponges appeared to host specific microbial symbionts, similar to the previously identified clones termed "OSO" environmental samples. In contrast, seawater samples near *Axinella* were dominated by *Pseudoalteromonas.* Adjacent sediment samples yielded clones of Planctomycetacea, Proteobacteria, sulfate-reducing *Desulfovibrio* spp, and other Deltaproteobacteria. Anaerobe-like 16S rRNA sequences were detected after the oxygen supply to one *Axinella* sample was deliberately curtailed to assess temporal changes in the microbial community. *E. caribaeorum* yielded more Betaproteobacteria relative to *Axinella* 16S libraries, and also included the Gammaproteobacteria genus *Spongiobacter*. However, *Axinella*-derived microbes appeared phylogenetically deeper with greater sequence divergences than the coral. Overall this study indicated that marine microbial community diversity can be linked to specific source hosts and habitats.

Keywords: Sponge, coral, heterotrophic bacteria, 16S rRNA, symbiont

Introduction

Studies of microbial ecology and diversity in the oceans have accelerated over the past decade, partially due to advanced 16S rRNA and metagenomic sequencing methods (Venter et al. 2004; Sogin et al. 2006), plus the recognition of some pivotal microbial functions that include ecosystem services, biogeochemical cycles and symbioses with eukaryotic hosts (Torsvik et al. 2002; Hill et al. 2006; Taylor et al. 2007).

Along these lines, our laboratories have studied marine sponge species for several years. This research includes *Axinella corrugata (Ax)*, a common reef sponge of the Caribbean and Western Atlantic. This bright orange sponge has become a model for natural products chemistry, cell biology, molecular and population genetics (Lopez et al. 2003; Pomponi 2006). Some sponge species have a microbial biomass reaching over 50% (Santavy and Colwell 1990; Fieseler et al. 2004). Similarly, corals have been shown to possess unique and diverse bacterial populations (Rohwer et al. 2001; Ritchie and Smith 2004), but some coral species appear susceptible to bacterial disease outbreaks (Ritchie et al. 2006; Halpern et al. 2008). In addition, the coral, *Erythropodium caribaeorum* (*Ec*) has been shown to produce a wide variety of biologically active diterpenes, such as the anti-mitotic agent eleutherobin (Cinel et al. 1999), and the briarane (erythrolides) and aquariane (aquariolides) skeletal classes (Taglialatela-Scafati et al. 2003).

Longstanding questions regarding the role of microbes in these marine invertebrate hosts, coral reef diseases and potential marine natural product biosynthesis remain. Could coral disease reservoirs exist in other invertebrate species

besides corals, and then jump to reef builders when environmental conditions change (Harvell et al. 2002)? Does the ultimate source of potent natural products stem from resident, symbiotic microorganisms? To provide some baseline data for answering some of these questions we have applied molecular microbiological methods to define the microbial populations associated with these invertebrates and their environments (Sfanos et al. 2005).

Methods

Both coral and sponge hosts are relatively shallow benthic species: *E. caribaeorum* was collected by SCUBA off Fort Lauderdale, Florida at a depth of 30 fsw (feet seawater). *A. corrugata* specimens were collected between 80 – 120 fsw depth off San Salvador and Little San Salvador, Bahamas in 2002. Specimens of *A. corrugata* were held in running seawater for several days to examine short-term temporal changes in the microbial community. One additional specimen was placed in a container with no running seawater to investigate microbial changes under anoxic conditions.

Genomic DNA was rigorously extracted from sponge tissues using a modified guanidium isothiocyanate method (Lopez et al. 2002). Sponge mesohyl (tissue) was obtained from the center of the sponge prior to homogenization Typically 0.5 – 1.5 g sponge mesohyl samples were ground to a fine powder in liquid nitrogen, and incubated for about one hour at 37^{o}C in 5-10 ml of GES (60% [w/v] guanidium isothiocyanate, 20 mM EDTA, 0.5% sarcosyl). DNA from marine sediment samples was extracted using a bead beating method (Mo Bio "UltraClean" soil DNA extraction kit, Solano Beach, CA) according to the manufacturer's instructions.

16S small subunit rRNA sequences were generated by PCR and universal 16S rRNA primers using standard methods previously described (Sfanos et al. 2005). Templates for the cloned 16S rRNA libraries were two different *A. corrugata* specimens. All culture-independent library sponge clones begin with a number, such as "354e", whereas cultured isolates begin with a letter such as T473 etc (also see Sfanos et al. 2005). *Ax* isolates in this study included T295, T266, T274, T288, T473, T273, T280, T456, , T479 S982, and J586 (also see http://www.hboi.edu/dbmr/dbmr_hbmmd.html; Gunasekera et al. 2005). 16S clones derived from *E. caribaeorum* are labeled with "EC".

Sequence and phylogenetic analyses

After confirmation of the closest sequence relative in GenBANK via BLASTN analyses (Cole et al. 2003), new *Ec*-derived sequences were deposited into GenBank and given accession numbers DQ889871-DQ889940, while *Ax* culture independent 16S and isolate sequences had the following GenBank numbers: FJ215389-FJ215423, FJ215474 - FJ215549, and FJ215561-FJ215629.

The program FastGroup II (Yu et al. 2006) was used to perform species richness estimates and rarefaction analyses of individual *Ec* and *Ax* libraries.

Phylogenetic analysis began by aligning sequences using CLUSTALX (Thompson et al. 1997). After manually checking alignments by comparing with known secondary structure models (Sfanos et al. 2005), poorly aligned SSU rRNA regions (e.g. high number of gaps or indels) were omitted from further analysis. Alignments were then imported into PAUP (phylogenetic analysis using parsimony) v 4.0b3a (Swofford 2000), which allowed a comparison of various phylogenetic algorithms and substitution models. Due to the high amount of sequence divergence in most rRNA datasets, minimum evolutionary tree topologies based on distance models were obtained using heuristic methods. Each reconstructed group was statistically evaluated by bootstrapping with a minimum number of 200 replicates (Felsenstein 1985; Nei and Kumar 2000). Most appropriate DNA substitution models for each algorithm were determined using MODELTEST (Posada and Crandall 1998). Reference and type sequences were also downloaded from GenBank in order to help identify specific sequence clusters.

Table 1: Bacterial 16S rDNA clones derived from *A. corrugata (Ax*), *E. caribaeorum* (*Ec*) and environmental samples associated with *Ax.*

Results/Discussion

A total of 110 and 98 16S rRNA clone sequences were sequenced from five different *Axinella* libraries and *Erythropodium*, respectively. Environmental sample libraries were also generated from sediment (39 clones) and water samples (36 clones) collected adjacent to the *Axinella* samples.

Table 1 shows comparative profiles of culture-independent 16S rRNA sequences derived from the two invertebrates and the sediment and water samples collected adjacent to the San Salvador *Axinella* samples.

Among some of the interesting *Ax* sponge-derived sequences, clone 363AM had 96% similarity with an *Arcobacterium*, and several clones had the closest similarity to *Bdellovibrio* and spirochaetes. In addition to the *Arcobacterium*, several additional sequences weakly matching (<90%) to Epsilonproteobacteria were also found in *Axinella,* but are not included in Table 1 at this time, pending verification. A *Nitrospira* clone, 345AU, was also identified. The sponge was further distinguished by the higher proportion of Delta-Proteobacteria and unknown microbial taxa (such as 345 BO, and 345 BM), relative to *Erythropodium.*

The diversity of cultured isolates from *Ax* comprised members of the Alpha-, Gamma- (*Alteromonas* spp*, Pseudoalteromonas* spp. and *Vibrio* spp.) and a few Betaproteobacteria, *Brachybacterium paraconglomeratum* (Actinobacteria) was also found.

The most striking similarity between the two benthic invertebrates, despite geographic and taxonomic separation, was a high representation of the Proteobacteria, especially Gamma-proteobacteria. In contrast, Betaproteobacteria-like sequences were not recovered from the sponge, but represented 32% of all bacteria in *E. caribaeorum.*

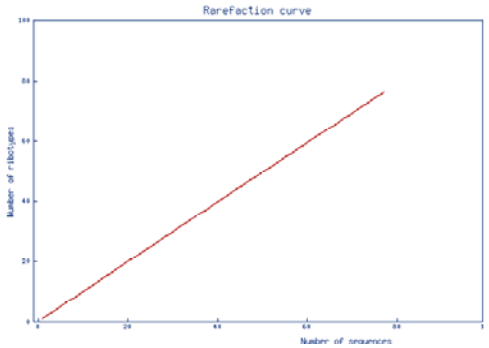

Figure 1: Rarefaction curve of one representative *Axinella* library based on 77 sequences.

About 83% of the *E. caribaeorum* sequences were representatives of the Proteobacteria, 6% of the clones were from cyanobacteria, 2% came from each of the Bacteroidetes, Actinobacteria, Acidobacteria, and Planctomycetes, while ~1% of the clones were represented by each of the *Chloroflexi,* Lentisphaerae and Verrucomicrobia taxa (Table 1).

In the coral, the largest fraction of the Proteobacteria were Betaproteobacteria (32%), followed by Gammaproteobacteria (30%), Alphaproteobacteria (15%), and Deltaproteobacteria (4%). There was only a single Epsilonproteobacteria (Table 1). The genus *Spongiobacter* dominated the Gamma-proteobacteria subdivision in this dataset. Dominating the Betaproteobacteria were representatives of the genus *Aquaspirillum*, followed by a number of clones that had "uncultured or unidentified" designations upon BLAST analysis. Moreover, six *Ec* clones showed high similarity to cyanobacteria sequences.

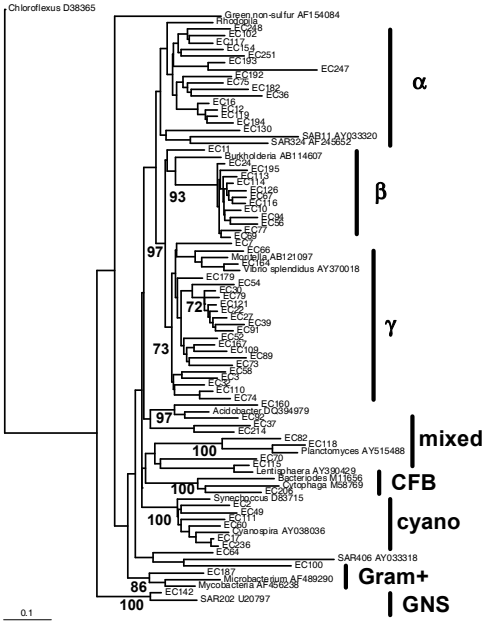

Figure 2: Neighbor-joining tree of *Erythropodium*-derived bacterial 16S rRNA. Reference sequences are listed with their GenBank numbers. Tamura-Nei correct model was implemented. Numbers below nodes are bootstrap percentages after at least 100 iterations. GNS = green non-sulfur bacterial cluster which includes *Chloroflexi.*

The rarefaction curve based on the *Axinella* 16S rRNA sequences shown in Fig. 1, confirmed that sequencing and microbial diversity analyses for this species were not exhaustive. More diversity

may be surveyed by using different 16S rRNA universal primers or DNA extraction methods.

Phylogenetic analyses

Taxonomic diversity within each invertebrate host is partially reflected in the neighbor-joining trees of *E. caribaeorum* and *A. corrugata* 16S rRNA sequences shown in Fig. 2-3, respectively. The analysis was performed primarily to provide a better understanding of taxonomic placement rather than determination of precise phylogenies of bacterial lineages. Nonetheless, the trees highlight the dominance of Proteobacteria in both species. In the *Axinella* tree, triangles denote likely species-specific symbionts (found in >1 specimen). The larger Gammaproteobacteria cluster appeared distinct from other cultured Gammaproteobacteria (e.g. *Vibrio* clade). Several bacteria cultured from

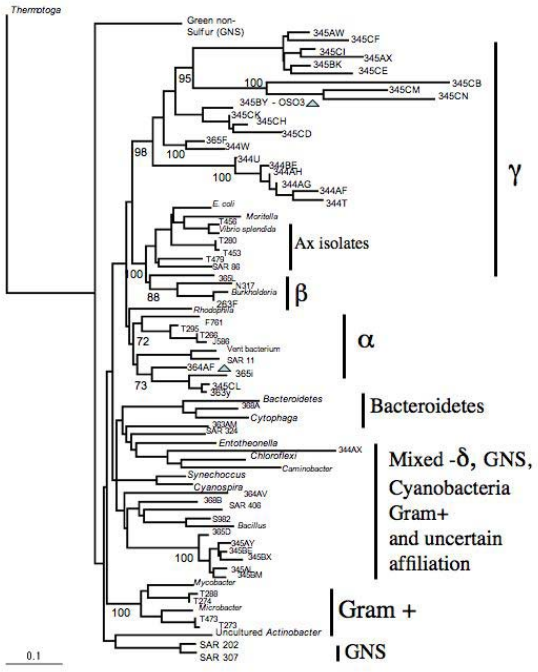

Figure 3: Neighbor-joining tree of *Axinella*-derived 16S rRNA clones. Tree reconstruction parameters and designations follow those shown for *Erythropodium* in Figure 2. A total of 77 bacterial taxa are shown.

Ax ("*Ax* isolates") appear dispersed to either the Gammaproteobacteria cluster or in the Gram+ and Alphaproteobacteria clusters at the bottom of the tree. Not all *Ax* isolates were included in the tree of Fig. 3, but the sequences have been submitted to GenBank. The previous study of cultured sponge isolates of Sfanos et al (2005) showed that most could be identified to family or genus. In contrast, several "unknown" and *Chloroflexi* bacteria were observed from these sponge culture-independent clones.

In the coral, sequences within all Proteobacteria clusters appeared less divergent, with shorter branch lengths, than *Axinella.*

These studies add to the evidence for symbiont specificity in *A. corrugata,* specifically adding to the data on "OSO" ("Orange sponge") studied by Hill et al (2006). OSO 16S rDNA sequences were found in multiple studies of geographically separated *A. corrugata* specimens. The OSO were not found among ~600 other clones generated from other sponge host species (data not shown; Lopez in preparation).

In contrast to the findings with OSO, the Gammaproteobacteria sequences derived from sediments adjacent to *Axinella* samples was uniform and dominated mostly by *Pseudoalteromonas* spp. which were not seen in the mesohyl/tissue libraries of either invertebrate.

Overall, we posit that microbial diversity patterns for both invertebrates generally reflect host species or geography, due to similar depths and water temperature of the specimens. However we cannot completely rule out temporal effects. In a limited time course experiment, some of the *Ax* clones were derived from a specimen that was oxygen deprived; this revealed an anaerobic clone (368B) with similarity to a *Clostridium*.

Although *Bacteroidetes* sequences were detected, this study did not find large occurrences of microbes previously associated with coral diseases such as *Roseobacter* and *Marinobacter* in either host reservoir. However, as the rarefaction analyses indicated, it is very possible that the sampling of total sequences remained below saturation.

It has been demonstrated that many bacterial communities associated with hard corals are largely coral species-specific, with microbial profiles reflecting phylogenetic relationships among coral species (Ritchie and Smith 2004). Previous molecular studies of hard corals have shown that the associated microbiota can be extremely diverse in species richness and abundance (Cooney et al. 2002; Rohwer et al. 2001). The same findings appear to hold for sponges, and other marine invertebrates that can serve as microbial hosts. Although a complete census of marine microbial diversity has certainly not yet been reached (http://icomm.mbl.edu/), microbial profiles are now extended with this study and with the continuing advances in high throughput sequencing technologies (Venter et al. 2004; Rusch et al, 2007).

Conclusions

The present data, in agreement with previous evidence, points to a suite of unique and interesting microbes that appear to be specifically associated with marine invertebrates.

Abstract. Diversity of gorgonians was investigated in the upper Gulf of Thailand and 15 genera were found. A field experiments determined the influence of cutting of branches on their growth rate. In *Menella,* non-cut colonies grew faster than cut colonies while in *Dichotella,* non-cut colonies grew slower than cut colonies.

Key words: *Menella*, *Dichotella*, gorgonian, diversity, physical disturbance

Introduction

The Indo-Pacific region has a high diversity of gorgonian corals (Goh and Chou 1996; Fabricius and Alderslade 2001; Dautova 2007). Their distribution and abundance are influenced by environmental factors such as light, temperature, water flows, currents, and substrates (Russo 1985; Weinbauer and Velimirov 1996; Zeevi and Benayahu 1999). Azooxanthellate gorgonians usually occur in mid-depth reefs and deep windward fore-reef terrace areas with high currents and sedimentation (Goh and Chou 1995; Goh et al. 1997; Sánchez et al. 1998). Gorgonians also act as refuge habitats for many small invertebrates such as crabs, snails, and brittle stars (Goh et al. 1999; Buhl-Mortensen and Mortensen 2005; Gili et al. 2006). Their shape and their complexity have an influence on diversity and abundance of associated animals (Buhl-Mortensen and Mortensen 2005).

In Southeast Asia, few studies exist on diversity of gorgonians (Alderslade et al. 1989; Goh and Chou 1996; Goh et al. 1997; Ofwegen et al. 2000; Ofwegen and Alderslade, 2007). In Singapore, 12 genera of gorgonians were found (Goh and Chou 1996). In Thailand, gorgonians are common and from previous records 28 genera are known (Alderslade et al. 1989; Worachananant 2000).

In this study, we investigated the diversity of gorgonians in the upper Gulf of Thailand. In addition, the influence of physical disturbance such as cutting on the growth was investigated.

Methods

The surveys were conducted to investigate the diversity of gorgonians at 10 study sites of Mu Ko Samae San, Sattahip, Chonburi Province, the upper Gulf of Thailand (Fig.1). Gorgonians were sampled by scuba diving from 1-20 m depth. Since gorgonians taxonomy needs revision, specimens were only identified to genus level. The density of gorgonians at Laem Pu Chao, western part of Sattahip Bay was investigated with 3 belt transect lines (50 m each) at 6 m depth, where majority of colonies occurred. A diver swam along the line counting gorgonian within 2.5 m on either side.

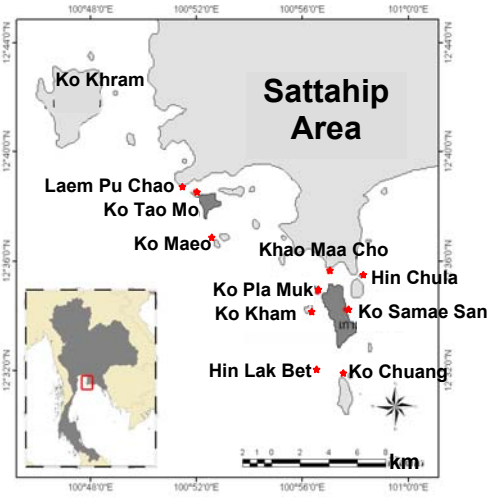

Figure 1: Ten study sites of gorgonians at Mu Ko Samae San, Sattahip, Chonburi Province.

To determine whether physical disturbance such as cutting would influence the growth of gorgonians, field experiments were conducted at Laem Pu Chao. Two genera, *Menella* and *Dichotella* were chosen. *Dichotella* was a dominant genus at Sattahip and *Menella,* although its density was not high in the study area, is a common genus throughout the Gulf of Thailand. Ten colonies of each genus were tagged at 6 m depth. Five of them were control with no

disturbance (normal colony group) while the other five were disturbed by cutting (cut colony group). In each disturbed colony, 5 branches were chosen. Two branches were cut to approx. 5 cm remaining in length (cut branch group) while another 3 branches were left without cutting (normal branch group). For undisturbed colonies, 5 branches of each colony were also selected. Each month, the growth of each branch in both disturbed and non-disturbed colonies were measured. The experiments continued for 16 months.

Results

A total of 15 genera of gorgonians were found at Mu Ko Samae San, Sattahip, Chonburi Province. These included *Subergorgia*, *Melithaea*, *Mopsella*, *Acabaria*, *Euplexaura*, *Echinomuricea*, *Echinogorgia*, *Menella*, *Paraplexaura*, *Astrogorgia*, *Rumphella*, *Guaiagorgia*, *Ctenocella*, *Junceella* and *Dichotella*. Two genera (*Paraplexaura* and *Guaiagorgia*) were the first record found in Thai waters, while three genera (*Echinomuricea*, *Menella* and *Dichotella*) were the first record in the Gulf of Thailand.

Total (15 genera)	10	11	6	7	6	1	10	6	4	5	

The highest diversity of gorgonians (11 genera) was found at Ko Tao Mo, followed by 10 genera at Laem Pu Chao and Ko Kham (Table 1). The density surveys at Laem Pu Chao showed that *Dichotella* was the dominant genus (59.1% of total gorgonian colonies found) followed by *Ctenocella* (18.4%). *Melithaea*, *Euplexaura* and *Rumphella* had the lowest densities (0.5%) (Fig. 2).

The field experiment on cutting showed that in normal colonies (control group), the percents of monthly relative growth rates of *Menella* and *Dichotella* were 4.7% and 0.6% respectively (Fig. 3). When comparing between cut and non-cut colonies of *Menella,* there was a significant difference in the growth rate (p<0.05). Non-cut colonies had higher percent relative growth rate per month than cut colonies (Fig. 3). However, in *Dichotella,* cut colonies had higher relative growth rate per month than non-cut ones (p<0.05) (Fig. 3). In cut colonies of *Menella*, even though cut branches seemed to grow faster than non-cut branches, there was no significant difference (Fig. 4). In contrast, there was significant difference in the growth rates between cut branches and non-cut branches in the cut colonies of *Dichotella* (p<0.05) (Fig. 4).

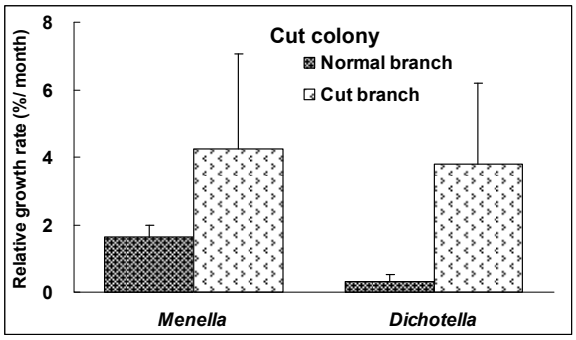

Figure 4: Percent relative growth rate per month of cut and non-cut branches in *Menella* and *Dichotella.*

Discussion

In Chonburi Province, upper Gulf of Thailand, 15 genera of gorgonians were found, a low diversity in comparison with other countries in Southeast Asia. In Indonesia, 225 species of gorgonians were recorded and in the Philippines, 36 genera (Mai-Bao-Thu and Domantay 1970; Grigg and Bayer 1976). Ko Tao Mo had the highest diversity (11 genera). Scleractinian coral species diversity was also high in this area (our observations). This may be due to high currents, one of the major factors influencing the diversity and distribution of gorgonians (Zeevi and Benayahu 1999; Fabricius and Alderslade 2001).

The field experiments showed that reaction to cutting differed between gorgonian genera. In *Menella,* energy needed for the regrowth of the cut branches lowered average growth in comparison to non-cut colonies. In *Dichotella,* cutting stimulated overall growth. More studies are needed for a better understanding of how those factors influence the abundance and growth of gorgonians populations.

The biogeography of damselfish skull evolution: A major radiation throughout the Indo-West Pacific produces no unique skull shapes

W. J. Cooper

Department of Biology, Syracuse University, 107 College Place, Life Sciences Complex, Syracuse, NY13244, USA

wjcooper@syr.edu

Abstract
The Indo-West Pacific (IWP) is the center of damselfish biodiversity (Perciformes, Pomacentridae), but phylogeographic evidence indicates that most of the pomacentrids in this region belong to a single lineage that diverged 12-18 million years ago. A strong majority of these species can only be found in coral communities, and this clade represents a major radiation of coral reef fishes within the IWP. Although these fishes constitute approximately half of the damselfishes (183 of 376 species), the results of morphometric analyses indicate they do not possess any unique cranial shapes, and the results of rarefaction analyses reveal that their skull morphology is significantly less disparate than the cranial diversity of the other damselfish clades. The pomacentrid skull shapes that are not represented within this lineage belong to fishes that inhabit rocky reefs. If only species from predominantly coral reef genera are compared, then there are no significant differences in skull shape disparity between these two groups. The Pomacentridae exhibit numerous examples of morphological and trophic convergence, and this tendency towards repeatedly evolving similar ecotypes is exemplified by the finding that a major expansion among the coral reefs of the IWP has produced no unique examples of damselfish skull anatomy.

Key words: Damselfish; Pomacentridae; Functional morphology; Fish feeding; Biogeography

Introduction

The Indo-West Pacific contains the planet's greatest diversity of coral reef fishes (Bellwood and Wainwright 2002a; Carpenter and Springer 2005; Mora et al. 2003) and deciphering the historical patterns of community assemblage in this region is a major goal for marine biologists. The damselfishes represent a significant component of the near-shore reef fish communities throughout the tropics (Bellwood and Hughes 2001; Floeter et al. 2008), and approximately 300 pomacentrid species inhabit the IWP (Allen 1991). In order to understand how the current patterns of IWP coral reef fish diversity have formed, it is therefore necessary to understand the historical biogeography of the Pomacentridae.

Until recently, very few studies have used well-supported phylogenies of large numbers of species to address questions of reef fish biogeography (Bellwood 1997), but fortunately there has been a marked increase in such efforts during the past several years (e.g., Bellwood et al. 2004; Fessler and Westneat 2007; Floeter et al. 2008; Streelman et al. 2002; Westneat et al. 2005). These studies are associated with a recent surge in molecular phylogenetic investigation, and multiple examinations of damselfish relationships have been an important part of this rapidly expanding body of work (e.g., Cooper et al. 2009; Jang-Liaw et al. 2002; McCafferty et al. 2002; Quenouille et al. 2004; Santini and Polacco 2006; Tang 2001; Tang et al. 2004). The most recent of these examines 104 species representing all 28 pomacentrid genera (previously 29), reorganizes portions of the taxonomy, and raises certain questions about the biogeographical history of damselfishes in the IWP (Cooper et al. 2009).

The Pomacentridae can be divided into 5 major clades, each of which now constitutes a separate subfamily (Fig. 1; Cooper et al. 2009). Of these clades, the sister lineages that have diverged most recently are the Abudefdufinae and the Pomacentrinae (Fig. 1). Although relatively recent in origin compared to the rest of the pomacentrid crown group,

the Pomacentrinae have undergone a tremendous amount of diversification, and they now encompass 16 genera, almost exactly half of the damselfishes, and nearly 10 times the number of species as their sister taxon (Fig. 1). Their distribution also spans a massive portion of the globe, with the extremes of their range defined by the eastern coast of South Africa, the Red Sea, the Ryukyu islands of southern Japan, New South Wales and New Zealand, and Easter Island (Allen 1991). Despite the fact that they have radiated over such vast distances, they have not colonized the Atlantic (ATL) or the Eastern Pacific (EP; Allen 1991).

In light of their obvious ability to radiate over large areas that contain warm coastal waters, the absence of the Pomacentrinae from the ATL and EP suggests that their access to these regions has been blocked by dispersal barriers. The most likely of these are the cool ocean waters south of Africa, the geological barrier presented by Africa and the Red Sea landbridge, and the East Pacific Barrier (EPB), which is a large expanse of deep open ocean (~5,000 km) with very little habitat suitable for near-shore fishes (Grigg and Hey 1992). Of these three, only the landmasses can be considered impermeable or "hard" barriers to coastal reef-fish dispersal, while the two purely oceanic barriers in question are "soft" barriers that have been shown to limit, but not prevent, colonization of adjacent ocean regions by reef fishes (Bowen et al. 2006; Briggs 1995; Dı́az de Astarloa et al. 2003; Fessler and Westneat 2007; Floeter et al. 2008; Grigg and Hey 1992; Hadley-Hansen 1986; Lessios et al. 1998; Lessios and Robertson 2006; Robertson et al. 2004; Rocha et al. 2005).

The geological barrier was not in place until the closing of the Tethys Seaway that once connected the ATL and Indian Oceans. This warm water marine dispersal route was blocked by the northward movement of the African and Arabian plates somewhere between 12-18 mya, an occurrence that is referred to as the terminal Tethyan event (TTE; Adams 1981; Bellwood and Wainwright 2002b; Blum 1989). The biogeography of the Pomacentrinae and the Abudefdufinae suggests that they diverged shortly before the TTE, with enough time elapsing between their split and the formation of the Red Sea landbridge for the Abudefdufinae to divide into ATL/EP and IWP lineages (Fig. 1-2; Cooper et al. 2009; Quenouille, et al. 2004). The Abudefdufinae also invaded the ATL/EP a second time, with this colonization occurring more recently, but before the final closure of the Panamanian isthmus 3.1 mya (Coates and Obando 1996). It is possible, but unlikely, that the TTE did not occur until after this second incursion of the Abudefdufinae into the ATL/EP,

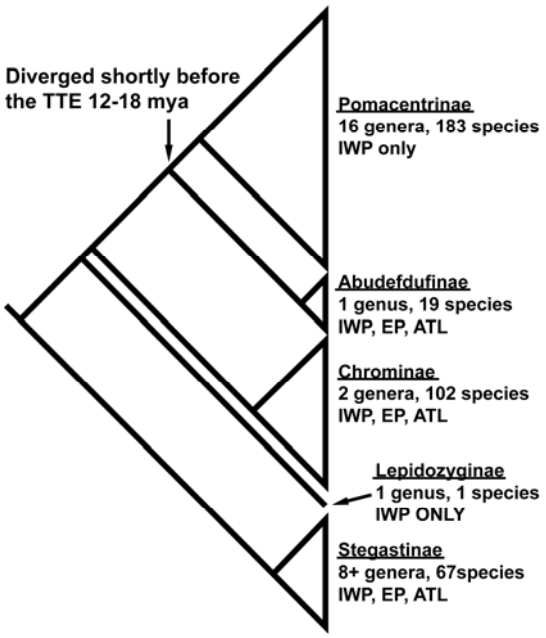

Figure 1. Phylogeography of the damselfish subfamilies. The listing of "8+" genera for the Stegastinae refers to the fact that "*Abudefduf luridus*" lies within this clade, and not with its current cogeners in the Abudefdufinae. IWP = Indo-West Pacific; EP = Eastern Pacific; ATL = Atlanctic. Phylogeny and taxonomy after Cooper et al. (2009).

but such a scenario would make it difficult to explain why the Pomacentrinae failed to invade the same region during this time. A more likely explanation is that the most recently derived species of *Abudefduf* in the ATL and EP colonized this region after the TTE by passing through one of the soft dispersal barriers listed above.

Regardless of the timing of their divergence, the Pomacentrinae represent a major radiation of reef fishes in the IWP that began relatively recently in comparison to the initial divergence of the damselfish crown group. Since the lineage is young (relative to the rest of the Pomacentridae), and since it contains such a large percentage of the damselfish diversity (>48.6 of the species, and >57.0 % of the genera), it is very likely that it has experienced rapid rates of speciation in comparison to the other pomacentrid clades. In order to determine if this lineage's rapid speciation and colonization of a large portion of the world's tropical oceans has been associated with the evolution of derived trophic morphologies, we chose to compare the functional anatomy of pomacentrid feeding between the Pomacentrinae and all other damselfishes.

Materials and Methods

Specimens

The heads of specimens (N=106) that represent all damselfish subfamilies, genera, and trophic classes (Allen 1999; Allen 1991; Cooper et al. 2009) were dissected in order to expose morphological landmarks of functional importance for fish feeding (Fig. 3). All specimens were adults except in the case of the genus *Altrichthys*, where only juveniles were available. Dissections were digitally photographed in lateral view, and 18 morphological landmarks (LM; Figure 3) were plotted on the image of each specimen using the program tpsDig (Rohlf 2006). This program was also used to determine the Cartesian coordinates of each landmark, and to establish the scale of all images.

Shape analyses

A relative warp (RW) analysis was used to display and quantify patterns of damselfish head shape diversity. The program tpsRelw (Rohlf 2007) was used to perform both a Procrustes superimposition of the data, and a RW analysis of the Procrustes transformed coordinates. Procrustes methods remove differences due to size, orientation and translation without distorting shape information. The RW scores of each specimen were used to map their location on RW axes. Distributions of the specimens in this "shape space" were used to describe relative morphological differences among individual skulls.

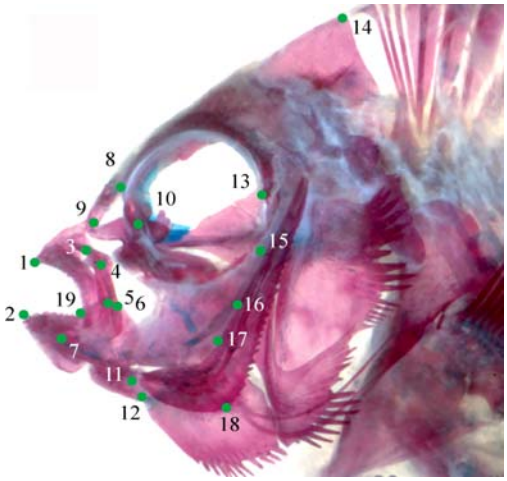

Figure 3. LM examined using RW analysis on a cleared and stained head of *Amphiprion akindynos*.

Comparisons of morphological disparity

In order to statistically compare differences in morphological diversity (shape disparity), a series of 4 different disparity metrics were calculated based on the scores for each specimen on the two largest relative warps (RW1 and RW2). These metrics were: sum of variances, product of variances, sum of ranges and geometric mean range (Stayton and Ruta 2006). Rarefaction of these calculations was then performed using the software application Rarify2 (Stayton 2006) in order to compare members and non-members of the Pomacentrinae using each type of disparity value. All groups were sub-sampled at sample sizes that ranged from 2 specimens to N-2 specimens (N = the number of specimens in each group). All 4 disparity metrics were calculated for 1000 iterations at each sampling level. Since almost all members of the Pomacentrinae are inhabitants of coral reefs (Allen 1991), a second series of rarefaction analyses were performed in order to examine the morphological evolution of only those damselfishes that utilize this habitat.

Results

Inspection of a RW score plot that displays the distribution of damselfish skull shapes along RW1 and RW2 indicates that the diversity of skull form exhibited by the Pomacentrinae is lower than the combined skull shape disparity of the more basal damselfish subfamilies (Fig. 4). The results of rarefaction analyses show that this difference in shape diversity is significant for all 4 disparity metrics at almost every sampling level (Fig. 5). The Pomacentrinae also appear to have evolved no unique skull shapes, since the region of shape space that they inhabit is almost entirely a subset of the region occupied by specimens from the other subfamilies (Fig. 4). Most of this difference is due to the head shapes of relatively large rocky reef inhabitants that evolved within the Abudefdufinae, Chrominae, and Stegastinae, and the exclusion of these specimens from the rarefaction analyses resulted in the elimination of significant differences (Fig. 4-5).

Discussion

The pomacentrinine damselfishes have undergone an extensive, and presumably rapid, increase in species diversity that has not generated any distinct skull morphologies. Since the anatomical landmarks examined in this study are components of the functional morphology of damselfish feeding, our results strongly suggest that this massive IWP radiation has not been associated with an expansion into completely new trophic niches. These findings therefore raise questions about how we can account for the success of the Pomacentrinae.

The results of investigations into the evolution of damselfish skull biomechanics using comparative phylogenetic methods (Cooper and Westneat 2009) indicate that the answers to some of these questions can be provided by observing how frequently damselfishes switch back and forth between a limited number of trophic niches. Almost all pomacentrids feed via herbivory, planktivory, or a limited type of omnivory that very rarely involves preying upon organisms that are highly elusive, durable or difficult to subdue. Although the variety of niches that they occupy is low, pomacentrids are able to quickly transition between them. The evolution of damselfish feeding is therefore characterized by rapid and repeated shifts between this limited set of ecological states, a pattern that has been described as a *reticulate adaptive radiation* (Cooper and Westneat 2009).

This propensity for convergence also applies to pomacentrids at the community level, since those fishes that inhabit coral reefs have repeatedly evolved similar trophic morphologies. The damselfish example, among others (e.g., Adams et al. 2009), demonstrates that evolutionary success need not be limited to lineages that continuously increase their anatomical diversity, but that it can also be achieved by organisms that do a limited number of things, but which somehow manage to do them very well.

Effects of coral mortality on the community composition of cryptic metazoans associated with *Pocillopora damicornis*

I.C. Enochs[1], G. Hockensmith[1]

1) University of Miami, RSMAS, 4600 Rickenbacker Cswy., Miami, FL 33149

Abstract. Coral reefs consist of complex three-dimensional habitats occupied by diverse taxa. The term cryptofauna (coelobites) specifically applies to those organisms that live within the interstices of coral reef framework. The remarkably diverse assemblage of cryptic biota in reefs is poorly understood relative to that of the epibenthic and nektonic reef species. It has been postulated that the biomass of this cryptic component of the reef ecosystem is high, possibly exceeding that of the surface biota. Furthermore, coelobites play an important role in reef trophodynamics and bioerosion. In order to evaluate the dependency of the cryptic community on the biotic nature of the substrate it occupies, both living and dead *Pocillopora damicornis* colonies were defaunated and returned to the reef. After six and twelve months *in situ*, associated coelobites were collected, identified, counted, and weighed. Communities associated with live coral colonies had greater biomass and were more similar than those associated with dead corals. These findings have important implications for how reef communities may respond to coral mortality.

Key words: cryptofauna, eastern Pacific, coral mortality.

Introduction

Coral reefs are considered to be the most biologically diverse ecosystems in the marine realm (Paulay 1997; Reaka-Kudla 1997). They maintain high biomass and high abundances of organisms despite their occurrence in what are classically considered to be oligotrophic regions. The majority of this concentrated biodiversity (Reaka-Kudla 1997) and biomass (Gischler and Ginsburg 1996) resides not on the surface of the reef but within the cavities of complex structural taxa and framework. Despite their prevalence, these cryptic species are poorly studied compared with the more accessible and charismatic surface fauna (Reaka-Kudla 1997).

Preliminary single taxon (polychaete) surveys have found coelobite densities to be as high as 127,900 individuals m^{-2} (Brock and Brock 1977). Another study found over 107 species living within a single colony of *Pocillopora damicornis* (Grassle 1973).

Although cryptic organisms spend most of their time hidden in cracks and crevices, they are functionally connected to both nektonic species and benthic epifauna. Coelobites are integral components of reef food webs and nutrient dynamics. They provide an essential energy source to many families of marine fish including Balistidae, Cirrhitidae, Haemulidae, Lutjanidae, Labridae, and Serranidae.

Energy, in turn, is incorporated into the coelobite community through a variety of different pathways. Cryptic suspension feeders capture and recycle particulate organic matter from surrounding reef waters (e.g., sponges, lithophage bivalves, polychaetes, barnacles: Richter and Wunsch 1999; Glynn 2008). Cryptic herbivores (e.g., amphipods, chitons, echinoids, limpits, opisthobranchs; Glynn 2008) feed on abundant supplies of algae which are all too often present on modern reefs. Carnivores (e.g., crustaceans, fishes, flatworms, nemerteans, gastropods, octopuses, polychaetes) are also prevalent in the cryptic environment and may exert a high degree of predatory pressure on the community as a whole (Glynn 2006, 2008). Cryptic coral symbionts have been found to benefit coral health and protect their host colonies from predation (e.g, *Trapezia ferruginea* and *Alpheus lottini*; Glynn 1983). Still other cryptic organisms (e.g., lithophage bivalves, polychaetes, sipunculans), play an active role in bioerosion, the biological destruction of coral skeletons and carbonate frameworks. These taxa effectively alter the reef habitat, providing shelters for other opportunistic cryptic species (Hutchings 1983) and ultimately reducing substrate complexity after coral mortality.

The composition of this important coelobite community is thought to be highly dependent on the surface area, volume, and porosity of the substrate it occupies (Hutchings 1974, 1983). Relatively little is known concerning the relationship of the cryptic community with the type of biological substrate it is associated. Some researchers have suggested that coelobite abundances are higher in areas of high algae cover. This may be due to a greater availability of food (Klumpp et al. 1988) or an absence of predation on settling larvae by the coral animal (Hutchings and Weate 1977). Despite these hypotheses, we are not

aware of any study that has directly compared cryptic community composition on living and dead coral.

A large and growing body of evidence has pointed to a worldwide decline in coral cover (Gardner et al. 2003; Bruno and Selig 2007) and increasing occurrence/magnitude of coral mortality events (Glynn 1993). The effect that coral death has on the diverse community of reef taxa is poorly understood. The few studies that have attempted to investigate the effects of coral mortality events have primarily focused on a single taxon (i.e., fishes). Assemblages of fish species have been found to change dramatically within short time periods after mass coral bleaching (mortality) events. Lindahl and others (2001) observed an increase in herbivore abundance and decrease in coral-associate abundance, resulting in an overall increase in fish species diversity. However, over longer time periods, a subsequent loss in habitat complexity may ultimately lead to lower abundance and diversity of fishes (Sano et al. 1987; Booth and Beretta 2002).

Because coral reefs are highly complex and diverse ecosystems, it is important to evaluate the response to coral mortality on multiple taxa assemblages. This study attempts to quantify the difference in community composition of invertebrates associated with live coral (*P. damicornis*) versus those associated with dead coral skeletons (six and eighteen months after mortality).

Material and Methods

Study Area:

This study was conducted at the Uva Island patch reef (7°48'52"N 81°45'34W), located in the non-upwelling Gulf of Chiriquí on the Pacific coast of Panamá. The reef is 2.5 ha and composed primarily of *P. damicornis*. Uva Island experiences a dry season from mid December through April and a wet season throughout the rest of the year. The wet season is characterized by light variable winds, higher rain fall, and higher cloud cover. During the dry season, thermocline shoaling may result in punctuated periods of lower water temperature and elevated nutrient concentrations (D'Croz and O'Dea 2007). Previous research on the Uva Island reef (Abele 1976; Glynn 1982, 1983) and others in the western Pacific (Grassle 1973; Patton 1974; Austin et al. 1980) has demonstrated the importance and prevalence of various taxa associated with the complex arborescent structure of *P. damicornis*.

The Uva Island reef has been extensively monitored by P. W. Glynn and others for the past four decades. Disturbances associated with the El Niño-Southern Oscillation (ENSO) have significantly impacted the area. Elevated water temperatures associated with the 1982-83 ENSO resulted in widespread coral bleaching and 75% mortality (Glynn 1984). The 1997-98, ENSO resulted in only13% coral mortality despite a similar thermal anomaly to the 1982-83 event (Glynn et al. 2001).

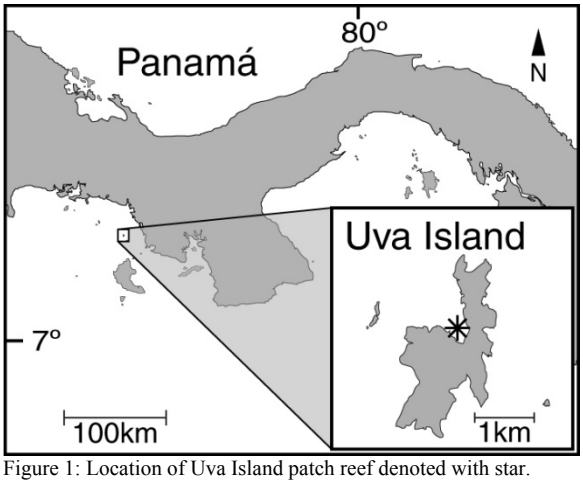

Figure 1: Location of Uva Island patch reef denoted with star.

Field Methods:

In September 2003 sixty colonies of *P. damicornis* were collected from the back reef at the Uva Island site. Maximum and minimum diameter and height were recorded for each colony. All associated metazoans were removed upon collection with aid of forceps and wire probes. Half (30) of the colonies were bleached with fresh water. Necrotic tissue was removed with a high pressure hose, leaving behind bare carbonate skeleton. Crosses were constructed from two pieces of one meter long iron rebar attached at their center. One dead and one living coral colony was affixed to each of two opposite ends of the cross. Live/dead pairs were randomly placed along the fore reef in approximately four to six meters of water.

In March 2004 (six months *in situ*) all experimental units were collected by sealing each colony in a plastic bag underwater. Bags were brought to the surface and each coral colony was defaunated using forceps and wire probes. Seawater from each bag was filtered over a 1mm mesh in order to collect those species that may have come free during collection. Colony dimensions were remeasured and each experimental pair was returned to the forereef. Cryptic metazoans were preserved in 70% ethanol and transported to the University of Miami Rosenstiel School of Marine and Atmospheric Science for further processing.

In March 2005 (12 months since defaunation) 23 of the original 30 experimental units were located and collected. It is likely that after 18 total months *in situ*, significant bioerosion occurred, resulting in the fragmentation and destruction of the missing pairs. Of those that were located, living coral colonies had grown to the point where it was necessary to break them apart in order to collect cryptic fauna. Dead colonies were

also broken apart to eliminate sampling bias. Water from each sampling bag was filtered over 1mm mesh and the dimensions of each colony were recorded. Again, metazoan associates were placed in 70% ethanol and transported to the University of Miami for analysis.

It is important to note that sessile taxa were not cleaned off of dead colonies after the first collection. Therefore, while communities of motile taxa collected in 2005 experienced 12 months *in situ*, the associated encrusting taxa would have developed for 18 months. Additionally, communities of motile fauna collected in 2005 would have experienced both wet and dry seasons during development while those collected in 2004 would have only experienced a single wet season.

Analysis:

Invertebrates were counted and identified to the lowest possible taxonomic level. The bulk wet weight of all individuals of each taxon associated with each colony was recorded. All specimens were deposited in the University of Miami Invertebrate Museum.

The geometric volume of each colony was approximated as a spheroid.

$$V = \frac{4}{3}\pi * \frac{wmax}{2} * \frac{wmin}{2} * \frac{h}{2}$$

Where *wmax* is maximum width, *wmin* is minimum width and *h* is height. Abundances, biomass, and richness were standardized (L^{-1}) by dividing the community parameters for each colony by the theoretical volume of that colony.

Differences in the abundance, biomass, and richness between live and dead colonies were investigated using t-tests and Mann-Whitney rank sum (MWRS) tests when the assumptions of parametric tests were not met. Differences between sampling years were not tested due to the possibility of sampling bias from the use of different methodologies to extract cryptic fauna.

A species by sample abundance (standardized to colony volume) matrix was constructed for each collection year. Abundances were square-root transformed in order to standardize the effects of abundant and rare species on the overall community assemblages. A similarity (Bray-Curtis) matrix was constructed for the transformed abundances using Plymouth Routines in Multivariate Ecological Research (PRIMER 5). The similarity matrix was used to construct an ordination by non-metric multidimensional scaling (nMDS) for each of the two sample years. A cluster analysis (group-average) was also conducted on the same similarity matrix and similarity levels of samples were drawn in the Euclidian space of the nMDS plots.

Results

Abundance:

A total of 1121 individuals were collected from live and dead colonies in 2004 and 4151 individuals were collected in 2005 (Table 1). There was no significant difference in abundance (standardized to volume) between communities associated with live and dead colonies in 2004. In 2005, dead colonies had higher volume-standardized abundances relative to live colonies ($P < 0.01$, MWRS). Proportionally, Crustacea was the most abundant taxon in 2004 (both live and dead) followed in order by Mollusca, Echinodermata, and Polychaeta. In 2005, Crustacea was again the most abundant taxon followed in order by Echinodermata, Mollusca, and Polychaeta. Several common species (mean abundance > 1 L^{-1} in either collection year) were found to be exclusively (e.g., *Alpheus lottini*, *Trapezia* juveniles and *Harpiliopsis spinigera*) or almost exclusively (e.g., *Fennera chacei*, *Pagurus benedicti*, and *Trapezia ferruginea*) associated with live corals. Other abundant species were found to be more closely associated with dead coral (e.g., *Teleophrys cristulipes*, *Palaemonella holmesi*, *Elasmopus* sp., and Gammaridea sp.).

Table 1: The abundance, biomass, and richness of invertebrate communities associated with living and dead *P. damicornis* in 2004 and 2005. Mean values (±SE) have been standardized to one liter by dividing the value for the community associated with each colony by the theoretical volume (approximated as a spheroid) of that colony.

Attribute	2004 (6 months *in situ*, $n = 30$)			2005 (12 months *in situ*, $n = 23$)		
	Live	Dead	Significance	Live	Dead	Significance
Mean Abundance individuals L^{-1}	21.4 (1.6)	22.1 (3.0)	ns MWRS	72.8 (12.2)	135.4 (21.8)	$P < 0.01$ MWRS

Mean Richness taxa L^{-1}	8.6 (0.5)	6.3 (0.5)	$P < 0.01$ *t* test	21.3 (1.4)	19.4 (1.2)	ns MWRS

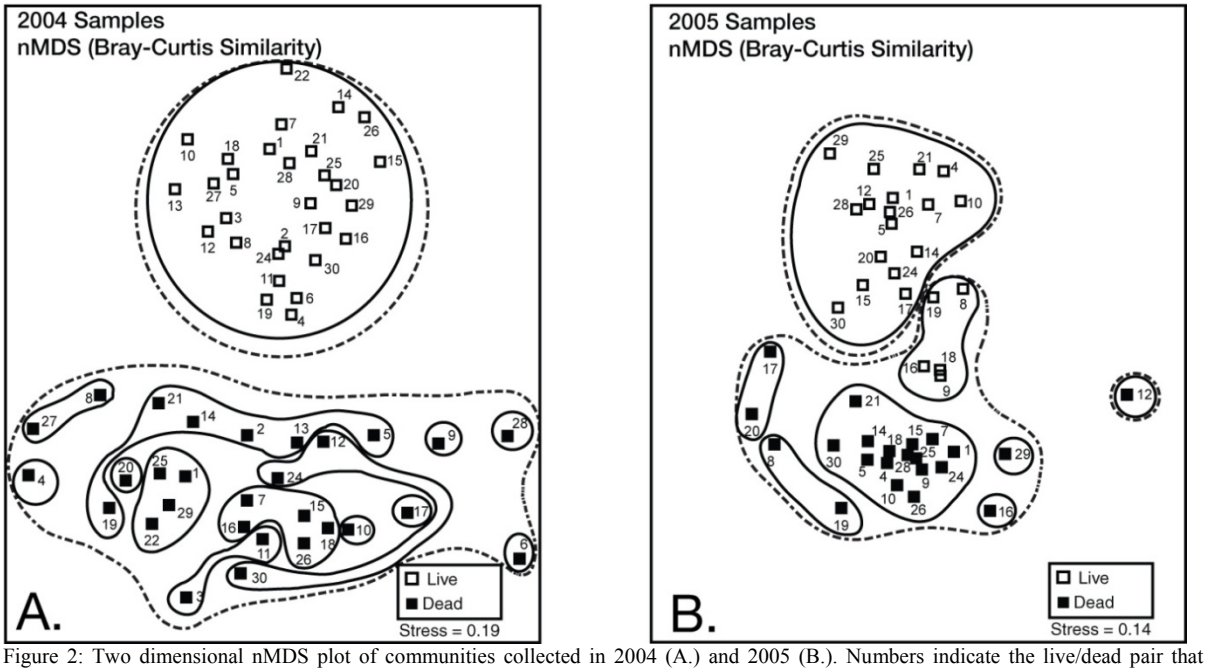

Figure 2: Two dimensional nMDS plot of communities collected in 2004 (A.) and 2005 (B.). Numbers indicate the live/dead pair that each community was associated with. Clusters superimposed at (A.) 22% (dashed line) and 43% similarity (solid line) (B.) 36% (dashed line) and 47% (solid line).

Biomass:

In 2004, 119.3 g of cryptofauna (wet weight) was removed from 30 live/dead pairs. In 2005, a total of 188.1 g of biomass was collected from 23 live/dead pairs. In both 2004 and 2005, the standardized biomass of the community associated with living coral was higher than that associated with dead coral ($P < 0.001$ and 0.01, respectively, Table 1).

Richness:

A total of 117 different taxa were identified (47 to species-level, 43 generic-level, 16 family-level, and 11 higher levels). There was a significantly greater number of taxa associated with living corals in 2004 ($p = 0.002$, *t*-test) but not in 2005 (Table 1).

Ordination:

The nMDS plot of samples collected in 2004 suggests that community composition was more similar between replicates for live coral associated coelobites than dead coral associates (Fig. 2A.). The same pattern was reflected in the ordination of samples collected in 2005. However, a group of five live-associated samples (9, 8, 16, 18, 19) were clustered more closely with dead-associated samples than other live (Fig. 2B.). Communities associated with dead coral in 2005 exhibited a large cluster of greater than 47% similarity which suggests a higher degree of similarity in the 2005 samples than in the 2004.

Discussion

The higher amount of biomass observed in communities associated with living coral colonies suggests a conferred advantage in the form of a greater availability of food and/or protection from predation. Food available to communities associated with a living coral could come from coral fat bodies (Stimson 1990), mucus (Coles and Strathman 1973), or from mucus-trapped plankton (Goldberg 2002). Protection for metazoan associates could be provided from the coral in the form of nematocysts. However, it should be noted that the stinging properties of the corals' nematocysts are ubiquitous and a degree of adaptation would be necessary for a given species to persist in their presence and benefit from their protection.

The qualification that live coral associates must be adapted to cope with the stinging behavior of coral nematocysts may help explain the high degree of similarity observed between live coral communities. Furthermore, several crustacean symbionts (e.g., *Trapezia ferruginea* and *Alpheus lottini*) have been found to be highly territorial and it is likely that they play a role in structuring the community associated with their coral host (Abele and Patton 1976).

The relatively low similarity between many dead coral communities can be explained by higher substrate heterogeneity compared with the live coral habitat. The availability of bare space immediately after coral mortality allowed colonization by a diverse assemblage of fleshy and calcareous algae, sponges, and cyanobacteria. A wider variety of food sources may have led to less specialized, more opportunistic species and consequently greater variability in community assemblages.

This study suggests that coral mortality may directly result in a reduction of cryptic biomass. It is likely that this will lead to a decrease in the biomass of higher trophic groups that directly (invertivore fishes and octopuses) and indirectly (piscivores fishes) utilize the cryptic community as an energy source. The collapse of both predator and prey populations after coral mortality could result in the cessation of important ecosystem functions and ultimately to ecosystem degradation.

It is possible that, given more time, algal growth may be able to support a higher amount of metazoan biomass on dead coral colonies. However, it is more likely that over these longer time scales bioerosion will result in a decrease in habitat complexity and subsequently near to complete cryptic community loss.

Because of the discrepancies in the two sampling years (differences in abundance and richness), it is important to use consistent methodologies to further evaluate seasonal variability and community succession. Furthermore, it is necessary to directly investigate the relationship between encrusting taxa that recruit to dead coral substrate and the motile communities that associate with them. As previously stated, it is likely that post mortality processes (substrate taphonomy, colonization by predator, prey, and territorial species) play in important role in the evolution of cryptic community structure.

Acknowledgement

Assistance with field collection was kindly provided by I Bethancourt, S Colley, P Fong, P Glynn, D Manzello, J Maté, T Smith, and A Simoes Correa. Identification of invertebrate specimens would not have been possible without the expertise of J Garcia-Gomez, P Glynn, A Graefe, L Harris, D Pawson, M Reaka-Kudla, and I Wehrtmann. V Brandtneris and A Costaregni provided valuable help with specimen processing. We would like to thank J Kool and B Riegl for their statistical advice as well as F Forrestal, P Glynn, D Manzello, and L Toth for their advice in writing this manuscript. This research would have not been possible without the support of the Smithsonian Tropical Research Institute, University of Miami Invertebrate Museum and funding from NSF (grant OCE-0526361 and earlier awards) to Peter W. Glynn.

Abstract. The abundance and distribution of marine algae was recorded for the first time in Madagascar Reef, a site that may be part of the connection between the Caribbean and the Gulf of Mexico algal communities. The objective of this study is to generate the base-line information on macroalgal functional forms (MFGs) distribution and abundances that can serve to develop a monitoring program for this community. We used the Steneck and Dethier (1994) functional-form system modified. MFGs were examined on 4 sites with three different substrates. The abundance of MFGs and taxa was recorded using a modification of the Braun-Blanquet method. Community differences were analyzed with regard to MFGs and algal taxa distribution. The macroalgal assemblages were found to be variable at the MFG level and widely distributed, except for some of the more complex ones, which tended to be absent in the more continuous rocky substrate. While community analysis at both, MFG and taxa levels revealed similar trends in relation to the type of substrate, we were able to detect important differences in the number of genera that constitute these MFGs. The most diverse site concerning taxa and MFGs composition is probably associated with a more heterogeneous substrate.

Key words: Macroalgae, Functional Forms, Gulf of México.

Introduction

The functional form model is generally used to understand ecological patterns in the diversity of the macroalgal flora. This model is based on the idea that a form-function relationship can be used to interpret distributional patterns in relation to different environmental factors (Littler and Littler 1984). Different models of functional-form groups have been proposed (Littler and Littler 1980; Steneck and Watling 1982; Steneck and Dethier 1994). For this study we used the Steneck and Dethier (1994) system but separated the green calcareous from the coenocytic, as proposed by Collado-Vides et al. (2005) and Phillips et al. (1997), to distinguish conspicuous algae such as *Caulerpa*, *Codium* from *Halimeda* and other cenocytic algae, taking into consideration the local flora composition and morphology.

Madagascar Reef is located between the more structurally complex communities of both the Caribbean and the Gulf of México, therefore the study of this site could help answer questions about connectivity in the flora of the two biogeographical regions. The objective of this study is to generate the base- line information on taxa and macroalgal functional forms distribution and abundances that can serve to develop a monitoring program for this peculiar community.

Material and Methods

Study Area

Madagascar Reef is located at the Northwest of the Yucatan Península, north of the port of Sisal (Fig.1). It forms part of the Inner Campeche Bank Reefs. It is an underwater extension of the Yucatan Peninsula that slopes gradually northwards for about 200 km and descends abruptly into the Sigsby Deep.

Four sites were selected. Site 1 was located at 21°26´26.1´´N and 90°16´55.2´´W, had 24ºC, was 15-17.5m deep and had a sandy substrate; Site 2 was located at 21°26´19.2´´N and 90°16´56.5´´W, had 26ºC, was 7-11m deep and had a mixed rocky-sandy substrate; Site 3 was located at 21°26´19.2´´ N and 90°16´42.3´´W, had 27 ºC, was 7-12m deep and had a rocky substrate; Site 4 was located at 21°26´29.6´´N and 90°17´36´´W, had 24ºC, was 15-17.5m deep and had a rocky substrate.

Field techniques

Between August and September of 2007 four sites were collected along the reef. Two 10m transects marked at 2m intervals were used at each site, with a 25 x 25 cm quadrant placed every two meters (to the

right, center and left of the transect, alternatively) to record the composition and abundance of each MFG (macroalgae functional group). In the field, the abundance of MFGs was recorded using the Braun-Blanquet method, assigning a "relative abundance score" between 0 and 5 in each quadrant (0=absent, 1=few to numerous individuals covering <5%, 2=5-25% cover, 3=25-50% cover, 4=50-75% cover, and 5=75-100% cover). Specimens were collected and taken to the laboratory to determinate taxonomic unit (species or genus) and confirm MFGs.

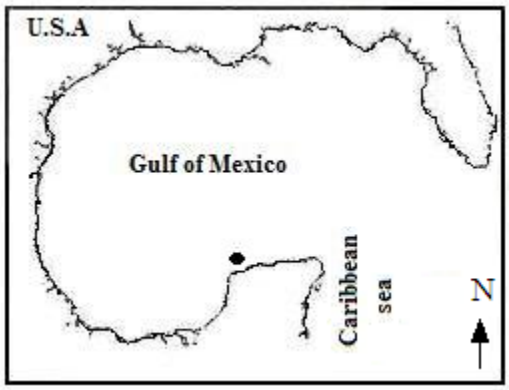

Figure 1: Geographical position of Madagascar Reef.

We used the Steneck and Dethier (1994) system, separating the coenocytic from the calcareous green. For purposes of analyses, data from these quadrates were averaged. Shannon´s diversity index was calculated and matrices with both species and MFGs were built. A percentage of similarity cluster analysis with UPGMA linkage procedure was applied in order to identify similarities in trends between sites, and a PCA was used to determine correlations between sites and species and MFGs using the MVSP 3.1

Results and Discussion

Composition

A total of 55 taxa (visible growth) was recorded (Table 1). At site 1, the most abundant taxa were *Gracilaria* spp, *Halymenia* sp, articulated calcareous algae and Cyanophyta whereas at site 2 the most abundant were *Asparagopsis* and *Dictyopteris* spp. At sites 3 and 4 the Rhodophyta had the highest number of taxa, but *Dictyota* spp and *Dictyopteris* spp (Phaeophyta) had the highest abundance. The least abundant group was the leathery macrophyte constituted by *Sargassum* (Fig. 2).

The 55 taxa were unevenly distributed across the 10 MFGs. The most diversified MFGs were the filaments, corticated polysiphonic filaments and corticated macrophytes, comprising over 50% of the taxa; and the least species-rich group were the foliose and leathery macrophyte, with only one taxon each (Fig.3-4).

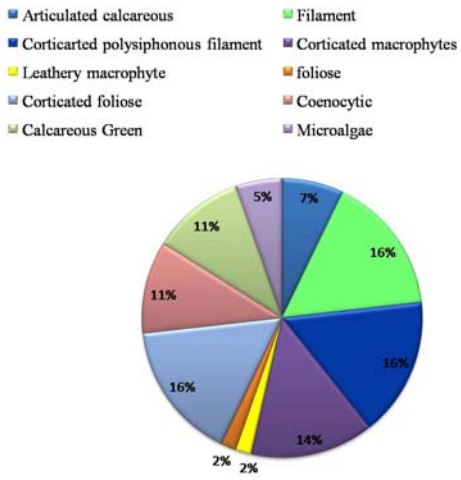

Figure 2: Abundance of different MFG at Madagascar reef.

Macroalgae Functional Groups

Ten MFGs were considered and their generic composition and distribution among sites was as seen in Table 1:

Concerning the abundance of MFGs per site, we found that sites 1 and 2 have eight and nine respectively; corticated macrophytes and the microalgae were the two most abundant at site 1, whereas at site 2 the most abundant were the microalgae, calcareous articulated and filamentous algae. Sites 3 and 4 both have six MFGs, the most abundant being the corticated foliose, the microalgae and the articulated calcareous (Fig. 3).

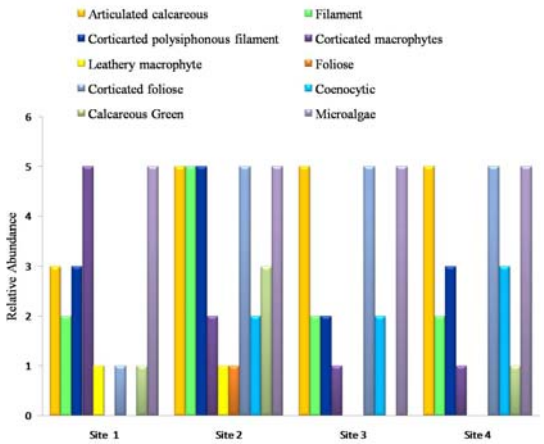

Figure 3: Relative abundance of MFGs per site.

The highest diversity was present at Site 2, both at taxa and MFGs levels, where all except the corticated

foliose group were found. Rocky bottom sites 3 and 4 showed a reduction of both taxa and MFGs, with very few calcareous greens and no corticated foliose algae, foliose and leathery macrophyte (Fig. 4).

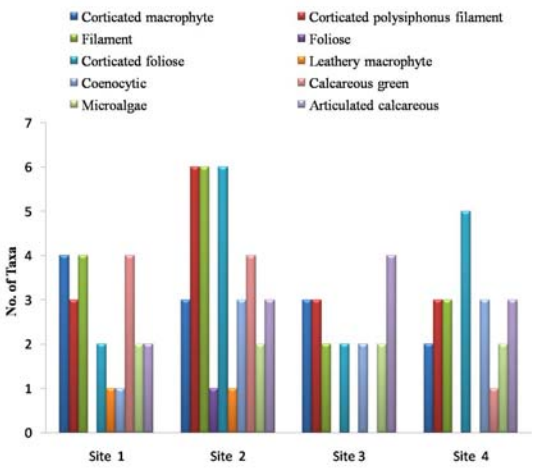

Figure 4: Diversity of Taxa/MGF and MFGs per site.

The PCA data indicate that axis 2 has 98% of the MFG abundance variability. For axis 2, the main component (MFG) that characterized site 1 were corticated macrophytes where *Gracilaria* had the highest abundance. In addition, for site 2 the main component were calcareous green (*Halimeda spp)*, corticated polysiphonous filaments (*Neosiphonia* spp), microalgae (*Lyngbya majuscula*), and filamentous algae (*Asparagopsis* spp.). For axis 1, the main component that differentiates sites 3 and 4 were corticated foliose (*Dictyota* spp), articulated calcareous (*Amphiroa* and *Jania* spp) and coenocytic algae (*Caulerpa* spp) (Fig. 5).

Analysis by MFG

The cluster analysis of similarity percentages indicates that site 3 and 4 had a 94 % similarity, grouping sites with rocky substratum and separating them from sandy and sandy-rocky substrata (Fig. 6).

An algal distribution and abundance pattern was found using MFGs: The macroalgal assemblages were found to be variable at the MFG level and widely distributed, specially regarding the more simple groups such as the filaments and corticated polysiphonous filaments that constitute the turfs, whereas some of the more complex ones, such as foliose and leathery macrophytes, tend to be absent in the more continuous rocky substrate.

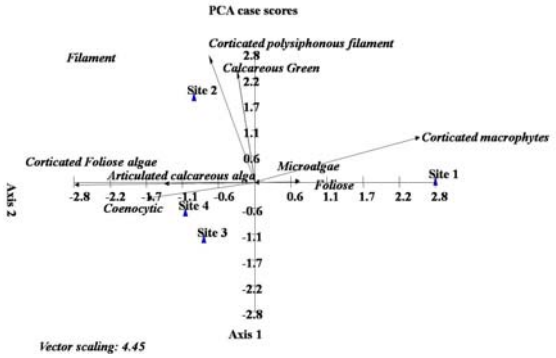

Figure.5: PCA analysis.

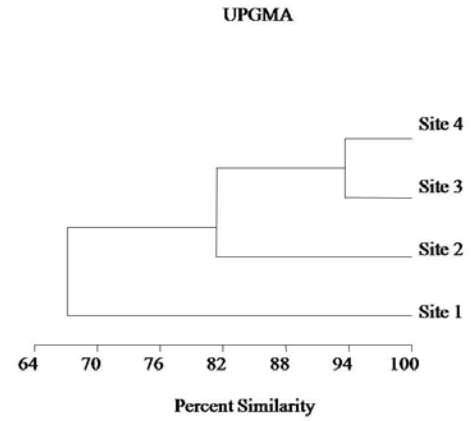

Figure 6: Classification dendrogram of Madagascar reef sites.

The most abundant MFGs at site 1 also belonged to the most abundant taxa (*Gracilaria, Halymenia* and *Lyngbya majuscula*), and the "corticated macrophyte" were the MFGs that covered the most area of the bottom. At site 2, a mixed substrate (sandy-rocky) allowed the presence of more MFGs with high abundance. Sites 3 and 4 had the same three groups with the highest abundance: coralline articulated, corticated foliose and the microalgae, the first two covering almost all the bottom forming a turf composed also in minor proportions by the other MFGs.

To detect any change within a community we first need to understand the spatio-temporal patterns. We still do not know whether the functional form group model provides the correct resolution to detect temporal and spatial changes in community structure, but it helps to provide a first insight on the way the algal community is structured. At this moment the similarity of results of using MFG and "genera" support its use as a rapid and efficient tool to study the spatio-temporal macroalgal distribution and abundance patterns in this type of communities.

Acknowledgement
We thank UMDI- Sisal personnel for the technical support and infrastructure provided for the development of this study. We also thank funds for field trips by UNAM and UADY. We are also grateful to Carlos Barrera and Juan Carlos Fuentes who helped with the collection of algal material and data processing.

Speciation extinction dynamics and the topography of diversity on Indo-West Pacific coral reefs

M.L. Reaka, [1], P.J. Rodgers[1], A.U. Kudla[2]

[1]Department of Biology, University of Maryland, College Park, Maryland 20742, USA
[2]Georgetown University School of Medicine, Washington, D.C. 20007, USA

Abstract. Profiles of diversity for reef mantis shrimps (Stomatopoda, Crustacea) demonstrate both latitudinal and longitudinal gradients across the Indo-West Pacific (IWP). The diversity summit in the equatorial Indo-Australian Archipelago (IAA) is 2-10 times higher than diversity to the west, east, north and south. From the IAA, diversity declines in the Indian Ocean (IO) but rises toward the African coast (IOC) and declines into the Central Pacific (CP). Endemism is highest in the IAA, high in the western IO and CP, but low in the mid-IO and western Pacific. Small-sized species in the IAA and IOC have restricted dispersal and higher rates of diversification than extinction, producing diversity centers with high endemism. IAA and IOC assemblages also include large species that produce enormous numbers of dispersive larvae, swamping divergence and preventing extinction in IO and western Pacific populations. In the CP, species become increasingly isolated and dwarfed; speciation is high but extinction even higher, yielding low diversity but high endemism. This model explains (1) why diversity gradients occur, (2) why "hotspots" (concentrations of diversity *and* endemism) occur in some but not other taxa (with different life history and dispersal constraints); and (3) why concentrations of endemism do not always coincide with diversity centers.

Key Words: Stomatopod, geographic range, endemism, body size, hotspots

Introduction

Gradients of diversity (species richness) on IWP coral reefs have been explained by the following 9 hypotheses, which range from historical and ecological to artifactual explanations. (1) Present centers of diversity are influenced by faunal carry-over and migration from an older Tethys sea-way center of diversity in Europe (Mesozoic onward; Briggs 2000, 2003a, 2007). (2) Plate tectonics carried antecedent biota and created complex topographic and oceanographic environments that fostered high rates of diversification in the IAA from the Miocene onward (Barber and Bellwood 2005, Barber et al. 2006). (3) Oscillating sea level changes, interacting with a complex topographic and oceanographic environment, changed land mass sizes and circulation patterns, especially during the Pleistocene, and affected marine speciation/extinction dynamics (Potts 1985, Paulay 1990). (4) Currents, originally coupled with the idea of high peripheral origination (Ladd 1960), caused accumulation of species (implying low extinction) in diversity centers (Jokiel and Martinelli 1991, Briggs 1995, Connolly et al.2003, Reaka et al. 2008). (5) The IAA diversity center results from conditions that foster high rates of origination (Center of Origin hypothesis, Briggs 1995, 1999a, 2000, 2003a, 2007). (6) The energy/productivity hypothesis (Rosenzweig 1995) proposes that, over evolutionary time, higher rates of energy flow through an ecosystem allow more species to co-exist (implying lower extinction rates). Viewed as a surrogate of energy input, temperature correlates with rates of speciation across latitudinal gradients (Allen et al. 2006, Allen and Gillooly 2006), but does not explain longitudinal diversity gradients in reef corals and fishes (Bellwood et al. 2005). Higher phytoplankton abundance generally corresponds with greater diversity and species body size in reef-dwelling stomatopods (Reaka 2000, Reaka et al. 2008). However, the rate of energy flow through an ecosystem may be best viewed as predation intensity across a trophic web. (7) Probably acting via species interactions such as predation and competition, species diversity itself correlates with rates of diversification (Emerson and Kolm 2005, Allen and Gillooly 2006). (8) Increased area is often associated with elevated diversity, probably because larger area increases habitat complexity, reducing extinction and allowing more species to coexist (MacArthur and Wilson 1967, Rosenzweig 1995, Losos and Schluter 2000, Bellwood and Hughes 2001, Hubbell 2001, Barber and Bellwood 2005, Bellwood et al. 2005). (9) The mid-domain effect (MDE) posits that random overlap of species ranges which are constrained by geography artificially generates centers of diversity (Woodland 1983; Colwell and Lees 2000; Colwell et al. 2004, 2005; Connolly 2005; McClain et al. 2007).

Although it explains some of the variance, the MDE does not play a major role in forming diversity gradients in IWP fishes and corals (Connolly et al. 2003, Mora et al. 2003, Barber and Bellwood 2005, Bellwood et al. 2005).

The standing crop of diversity at any one place ultimately results from the rate at which species immigrate and either persist, diverge into new species or go extinct. This is essentially the thesis of classical Island Biogeographic Theory (MacArthur and Wilson 1967) and the Unified Neutral Theory of Biodiversity and Biogeography (Hubbell 2001), although the assumptions of these 2 approaches (evolutionary equilibrium under deterministic conditions vs. random ecological drift among species) differ. Except for Jablonski et al (2006), the concept of immigration and speciation/extinction dynamics, however, has not usually been applied to latitudinal and longitudinal diversity gradients, and that is what we explore here.

Materials and Methods

All available IWP distributional records and individual body sizes for species of coral reef stomatopods (Alainosquillidae, Gonodactylidae, Odontodactylidae, Protosquillidae, Takuidae [but not Pseudosquillidae because of their very different reproductive, larval and life history patterns]) were collated, using current taxonomy, from our own and US National Museum collections and the published literature. These data were mapped to determine endemism and diversity. Typical body sizes of species from each region were analyzed according to both maximum and median body sizes of individuals in the population or species assemblage. The 6 biogeographic/habitat regions were chosen on the basis of habitat type (influenced by continents vs. open ocean) and biogeography (cohesiveness of faunas, relative geographic position from the western margin of the IO to the CP).

Results

The Topography of IWP Stomatopod Diversity

We present the first longitudinal transects of species diversity for coral reef stomatopods at 3 latitudes across the IWP (fig. 1). Stomatopod diversity in the IWP is strikingly monolithic—the summit of diversity in the equatorial IAA towers above that of the rest of the IWP in every direction. Less than half as many species are found in the western IO, western Pacific and higher latitudinal regions of the IAA (20°N, 20°S) as in the center of diversity around Indonesia, Malaysia and western New Guinea. Another much lower peak of diversity along the equatorial western margin of the IO climbs higher toward the south around Madagascar. In the IOC, diversities at the equator and 20°S are approximately double those at 20°N. At the West Pacific margin, diversities of the southern and equatorial transects are higher than (but not double) those at 20°N, but in the West Central Pacific, diversities are high only at 20°S in comparison to transects on the equator and 20°N. In the eastern IO (70-90°E) and especially the CP (170-140°W), diversity is strongly attenuated, declining to only 10-20% of that in the equatorial IAA.

Life Histories and Evolution in Stomatopods

Reef stomatopods are limited by the availability of bioeroded holes in the substrate due to intense fish predation (Reaka 1985, Dominguez and Reaka 1987, Steger 1987). Because small holes in the reef are vastly more abundant than large holes (Moran and Reaka 1988), territorial fighting and the possibility of not having a refuge increase—life becomes ever more risky—as species become larger in size. Yet increased body size confers behavioral (mating, fighting) and reproductive benefits.

Within lineages, large species of mantis shrimps grow faster, produce larger and exponentially more eggs with longer dispersal stages, reproduce more frequently, have broader geographic ranges, saturate a higher % of available habitat within their range, compete more intensely for refuges, exhibit more complex fighting and reproductive behavior and are more brightly colored than smaller species (Reaka 1979a,b; 1980, 1985, 1986, 1991; Reaka and Manning 1981, 1987a; Reaka et al. 2008).

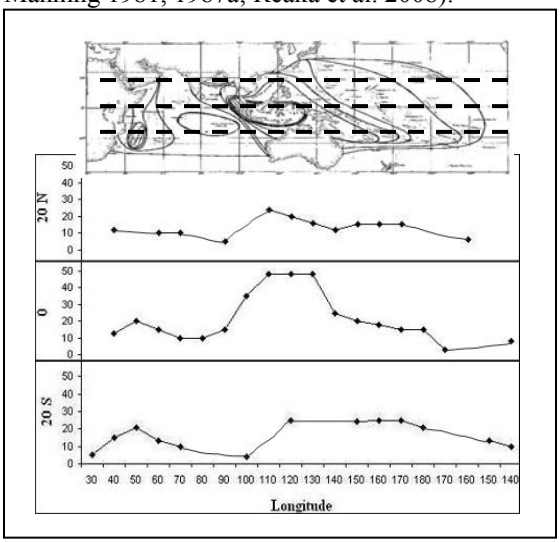

Figure 1. Longitudinal transects of diversity in reef stomatopods at the equator (0°) and at the margins of the tropics (20°N, 20°S). Number of species present at each longitudinal coordinate is indicated on the vertical axis for each transect. Degrees longitude is shown on the horizontal axis. Insect map shows continental masses, contours of diversity across the IWP, and positions of the 3 longitudinal transects (dashed lines).

In contrast, small adult body size is strongly associated with abbreviated larval development and restricted dispersal in marine invertebrates in general (Strathmann and Strathmann 1982; Jablonski and Lutz 1983; Strathmann 1985, 1990; Jablonski 1986a) as well as stomatopods. Small species of stomatopods are characterized by small geographic ranges and high endemism, relative rarity (low abundance, low saturation of available habitat within their range), major ecological innovations and occupation of reefs rather than level bottoms (Reaka 1980, 1986, 1991; Reaka and Manning 1981, 1987a; Reaka et al. 2008).

Because of its close relationship to the life history traits discussed above, body size strongly influences speciation in stomatopods. Large-bodied lineages and those with long-lived larvae remain conspecific or closely related even when separated for several million years by biogeographic barriers (e.g., the Central American Isthmus). In contrast, the % of species without close relatives elsewhere and within locally radiating lineages (more closely related to each other than to any species outside the region) are significantly elevated in small-bodied lineages, those with restricted larval dispersal and those inhabiting reefs. Only taxa of smallest body size within each of the major stomatopod lineages have invaded new types of habitat or adopted new feeding habits (Reaka 1980, Reaka and Manning 1987a).

Similarly, because of its influence upon life history traits and geographic distribution, body size is closely tied to extinction vulnerability in stomatopods. Although adequate fossil data are lacking, apparent extinctions—conspicuous gaps in distributions where extinction is the most parsimonious explanation—are significantly elevated among small-bodied species with restricted larval dispersal. Supporting this interpretation is the fact that, in other groups, species with low dispersal, low abundance and restricted distributions have been repeatedly shown to be more vulnerable to extinction over both ecological and evolutionary time than widespread dispersive taxa (Jablonski 1986a,b, 1987, 1991, 1994, 1995, 2008; Gaston 1994; Gaston and Blackburn 1996; Hubbell 2001; Jablonski et al. 2003; Hunt et al. 2005; Jablonski and Hunt 2006).

Speciation/Extinction Dynamics and Gradients of Species Diversity

Because of the correlation between body size and patterns of life history and evolution in stomatopods (and in many other marine species), body size can be used as a surrogate for the propensity to diversify and become extinct. Figure 2 depicts typical body sizes of reef stomatopod species across the IWP (x^2=11.07, df=5, p=0.02 for species above/below median body size of the 6 assemblages). Although the range in body size of each assemblage is large, especially from the IOC to the IAA, *most* species are diminutive in the diversity centers of the IOC and IAA, suggesting that these regions are hotspots of diversification and extinction. They also are hotspots of endemism (48% and 26% in the IAA and IOC).

Given their life history characteristics, large species in the IAA and IOC undoubtedly swamp the adjacent regions with larvae, accounting for the larger median body sizes of assemblages in the mid-IO and western Pacific regions. Populations in these adjacent off-shore regions are unlikely to diverge, and also are insulated from local extinctions, due to regular influx of larvae from ancestral populations and other large-bodied off-shore populations. Only 12% and 8% of IO and WPM species are endemic.

On the other hand, typical body size declines from the western Pacific regions toward the CP, with associated reductions in number of eggs and dispersal capability. This pattern is particularly exaggerated on atolls compared to high islands (Reaka 2000, Reaka et al. 2008), suggesting that Pacific populations are challenged by low productivity. Given enough time, larvae from large-sized dispersive species in the IAA and western Pacific must occasionally reach the CP, but, once there, the dwarfed populations are trapped, unable to produce enough propagules to reach another archipelago. If the population survives, divergence is almost inevitable due to selection and genetic drift. Endemism increases from 8% to 15% from the WPM to the CP. These founding populations also must frequently become extinct, especially in atoll environments that are characterized by low terrestrial input, high predation, smaller body sizes and lower reproductive capacity than high islands. We have directly observed extinction of 1 such population/species after storm disruption of local habitat on a mid-Pacific atoll (Reaka and Manning 1987b).

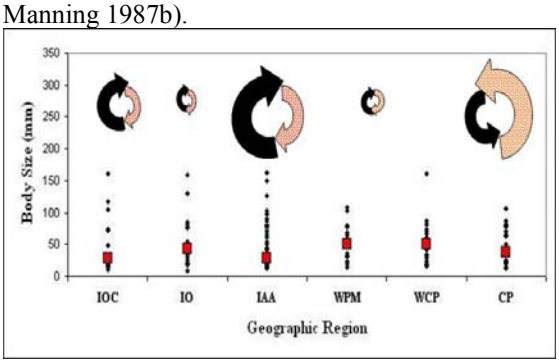

Figure 2. Body sizes of species assemblages of reef stomatopods at each of 6 biogeographic regions in the IWP (IOC=continental margin of the Indian Ocean, IO=open Indian Ocean, IAA=Indo-Australian Archipelago, WPM=western Pacific margin, WCP=West Central Pacific, CP=Central Pacific). Each dot represents maximal size of 1 species, squares represent the median body size of each regional assemblage, size of arrows represents relative strengths of speciation (black) and extinction (stippled).

Therefore, there are 3 centers of diversification in the IWP—in the diversity centers of the IAA and IOC but also in the remote and non-diverse CP. Body size of most species is diminished in all 3 regions, promoting genetic isolation and rapid speciation. However, the causative factors promoting small body size differ in the 3 regions. Biotic interactions (especially competition with other species of stomatopods for bioeroded refuges in the coral) likely are the main factors causing shifts toward predominantly diminutive body sizes (with consequent genetic isolation and rapid divergence) in the productive IAA and IOC. High reef community diversity also may provide more types of minute microenvironments for exploitation by small species in these areas. In contrast, low productivity likely causes dwarfism in the CP. Selection due to low productivity and predation, and especially isolation from western populations, probably are the main factors fostering rapid diversification in the CP.

The processes generating small body sizes and restricted dispersal ability in the IAA, IOC and CP, however, also constrain species to small geographic ranges and render them vulnerable to extinction. High rates of extinction in the IAA and IOC may even fuel higher rates of speciation, given abundant source populations (which is not true in the CP), since extinction continually re-opens niches. This leads to an accelerated cycle of speciation and extinction in the diversity centers. Extinction is especially high, and is likely to overwhelm speciation, however, in the harsh isolated conditions of the CP.

Discussion

Consequently, the standing crop of diversity—as represented in any diversity gradient across a geographic realm such as the IWP—is necessarily a result of 3 processes: immigration, speciation and extinction. Immigration—dispersal from other ancestral and sibling populations—influences both speciation (or lack of it) and extinction (or lack of it). In reef stomatopods, this cycle is controlled by life history traits, especially the number and dispersal capability of propagules produced—which in turn are controlled by species body size—which in turn is controlled by ecological and environmental factors that may vary in different regions, such as along a longitudinal or latitudinal gradient. The standing crop of diversity at any one place is a result of how fast and in what direction the wheels of speciation and extinction are spinning (arrows in fig. 2). In the IOC and especially the IAA, the wheels of speciation/ extinction turn rapidly compared to the adjacent off-shore oceanic regions, and the rate of speciation exceeds that of extinction—yielding high diversity and endemism. The wheels of speciation/extinction also spin rapidly in the CP, but here in the reverse direction—extinction exceeds speciation, yielding low diversity but high endemism. This is *why* concentrations of endemics do not always coincide with areas of high species diversity, *why* "hotspots" (areas in which *both* endemics and high species diversity are concentrated) are not always congruent among different taxa, and *why* a longitudinal diversity gradient stretches across the IWP.

Acknowledgement

The authors thank Christopher D'Elia for pointing out at the ICRS that the patterns of immigration, speciation and extinction we presented resemble the ideas inherent in Island Biogeographic Theory, which we had not explicitly incorporated into our thinking previously.

Abstract. The internal transcribed spacer 2 (ITS2) is part of the nuclear ribosomal cistron, whose secondary structure has important functions for ribosome assembling. Contrasting results in terms of inter- and intra-specific ITS2 variation have been found in a number of taxa including reef cnidarians. Different findings such as single or multiple intragenomic variants, even pseudogenes, have brought a great deal of confusion regarding the evolution and usefulness of ITS2 for phylogenetic reconstruction as well as the generality of the nRNA concerted evolution process. We examined intragenomic ITS2 copies in Caribbean seafan octocorals *Gorgonia* and *Pseudopterogorgia* (Gorgoniidae: Octocorallia) using Denaturing Gradient Gel Electrophoresis (DGGE) coupled with DNA sequencing and prediction of RNA secondary structures. Candidate pseudogenes were seldom found but most intragenomic ITS2 variants were functional secondary structures. Intragenomic variants were either dominant or codominant banding patterns in DGGE gels. Preliminary phylogenetic analyses showed that part of the intragenomic variation in *G. mariae* grouped partially with *Pseudopterogorgia* spp. as well as with other *Gorgonia* species. This finding supports the polyphyly of Caribbean sefans as observed with mitochondrial DNA and suggests a likely hybridization origination for *G. mariae*.

Key words: Intragenomic variation, ITS2, rDNA, Caribbean seafans, *Gorgonia*, hybridization, DGGE.

Introduction

The Internal Transcribed Spacer 2 (ITS2) is part of the ribosomal DNA cistron, which is transcribed but do not form part of the functional ribosomal complex. Although ribosomal genes are sequences repeated hundred of times in several chromosomes there are mechanisms that homogenize all the ribosomal genes (Elder and Turner 1995). Concerted evolution in ribosomal genes, although not entirely understood, is supposed to occur in a few generations owing a combination of processes such as intrachromosomal homogenization, gene conversion and unequal crossing over (Liao et al. 2000). Consequently, all copies of ribosomal genes are usually identical and can be considered single-copy genes for phylogenetic purposes. Nonetheless, ribosomal DNA intragenomic variation has puzzled molecular systematists and ecologists in the last few years.

The ITS2 attains higher evolution rates than other ribosomal genes. In addition, ITS2 has exhibited intragenomic variation in organisms ranging from plants to vertebrates. For that range of eukaryotes the intragenomic variation has been related to hybridization events (Coleman 2003). In the particular case of corals, however, it has been very difficult to explain the presence of intragenomic variants including a range of competing explanations such as incomplete lineage sorting, resulting in the preservation of ancestral polymorphisms, and introgressive hybridization (Volmer and Palumbi 2004). Opportunely, ITS2 is gaining credibility very fast. Coleman (2007), Schultz (2005) and Muller et al. (2007) are examples of some recent reviews showing generalities shared by all eukaryotes on several hallmarks of the ITS2 secondary structure, which have provided robustness using this sequence in phylogenetic and evolutionary studies. The function of the ITS2 secondary structure, unknown for many years, has a very important role during the ribosomal assembling. It is known experimentally that certain changes in the secondary structure prevent the formation of ribosomes (Cote and Peculis 2001, Van Nues et al. 1995). In addition, the same ITS2 sequence can turn into two different secondary structures, where the proximal part does not vary and it has an important function such as the C2 processing site and other parts of the molecule have a multifunctional role. Having that in mind, we can rely upon secondary structure to tell apart pseudogenes from functional ITS2 copies.

Seafans are shallow-water octocorals, which are very abundant in Caribbean coral reefs (Bayer 1961). Members of the family Gorgoniidae in this region are very diverse and have a symbiosis with zooxanthellae (Sánchez and Wirshing 2005). A particularity of gorgonians is their phenotypic plasticity (Sánchez et al. 2007, Gutierrez-Rodriguez et al. 2008), which enables them to colonize most reef habitats. However,

such variability imposes challenges to delineate species boundaries. Caribbean seafans comprise three species, *G. ventalina, G. flabellum*, and *G. mariae,* all of them include particular scaphoid sclerites (Bayer, 1961). Another characteristic of *Gorgonia* is the reticulate branching forming a mesh-like pattern, which is very dense in all species but *G. mariae*. Some of the growth forms in *G. mariae* are pinnate with occasional fused branches, resembling the genus *Pseudopterogorgia*. Of particular interest, molecular phylogenetic analyses among gorgoniids present different results regarding the position of *G. mariae*, mitochondrial DNA place it with *Pseudopterogorgia* spp. (Sánchez et al. 2003) whereas nuclear DNA (ITS2) with the other *Gorgonia* species (Aguilar and Sánchez 2007). Such incongruence between molecular phylogenies together with the intermediate branching characteristics of *G. mariae*, resembling both *Pseudopterogorgia* and *Gorgonia*, suggest a hybrid origin for this species (see reviews in Seehausen 2004and Mallet 2005). To approach the previous problem, we had two major goals in this study: first was to examine the nature of ITS2 intragenomic variation in seafans and sea whips (*Pseudopterogorgia*), and second to reconstruct preliminary phylogenetic hypothesis of ITS2 intragenomic variants.

Material and Methods

We studied the intragenomic variation in *Gorgonia* spp. and a few species of *Pseudopterogorgia*. We had fresh and museum material from Colombia, Panama, Belize, Puerto Rico and Bahamas. Total DNA was extracted using a CTAB, proteinase K, Phenol – Clorophorm-Isoamyl alcohol extraction method (Coffroth et al. 1992). DNA was resuspended and conserved in TE buffer at –70ºC. DNA quality was checked in agarose (1%) electrophoresis at 80V for 30 min. Using the best DNA extraction quality, primers 5.8s 5`-AGCATGTCTGTCTGAGTGTTGG-3` and 28s 5`-GGGTAATCTTGCCTGATCTGAG-3` designed by Aguilar and Sánchez (2007) were used for the ITS2 amplification, conditions for PCR were as follows: an initial denaturizing step: 2 min at 94ºC, followed by 35 cycles: 30 sec. at 94ºC, 30 sec. at 56.8ºC and 1 min at 72ºC, final extension step: 2 min. at 72ºC. Using 1 unit of Taq polymerase (Invitrogen), 3.5 mM MgCl2, 0.2 mM DNTPs (Biorad Mix), 0.15 uM primers (each) and 4µL of DNA (dilution 1/50) in 20µL as final volume. The amplification was standardized with an efficiency of 95%. PCR reactions were screened in a gel containing 8% polyacrilamide, 1X TAE Buffer and linear urea-formamide denaturing gradient from 45% to 80%. The gels were pre-run at 60ºC and 90V for 30 min, followed by the electrophoresis at 60ºC and 90V for 13 h. Gels were stained with ethidium bromide during 15 min and visualized using a BioRad ChemiDoc system. All reactions were conducted without CG-clamp in the primers. Bands visualized in the DGGE gel were excised using sterilized micropipette tips in the BioRad ChemiDoc system and placed in 1,5 mL tubes with 100µL of sterilized double distilled water. The tubes were incubated in a shaker at room temperature for 24 hours at 150 rpm. Each band extract was collected in a 1,5 mL tube and the DNA was precipitated with 300 µL of cold absolute ethanol, tubes were placed at -20ºC for 24 hours and then centrifuged at 13000 rpm for 30 min, supernatant was discarded and pellet dried and resuspended in 15 µL sterilized double distilled water.

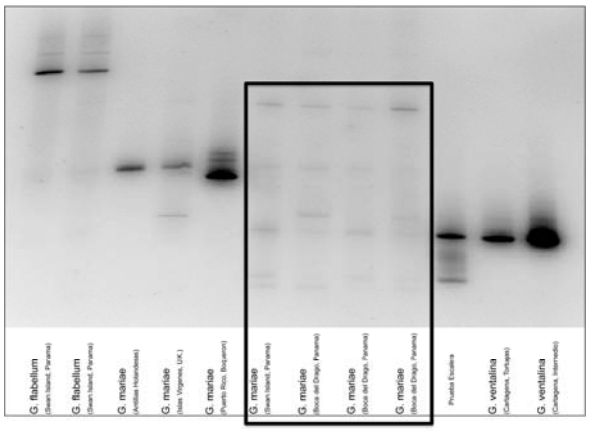

Figure 1: Examples of ITS2 DGGE banding patterns from seafans *Gorgonia* spp. colonies. Inset square: banding patterns of *Gorgonia mariae* from Panama (Bocas del Toro). Linear urea-formamide denaturing gradient of 45% to 80%.

Re-amplification of bands was conducted using PCR as described above except that DNA was used without dilution. Purification of PCR products for sequencing was performed by Exo-Sap method using 1 u of Exonuclease, 0,2 u of Shrimp Alkaline Phosphatase and 2µl SAP buffer 10x per 20 µl in a 0,2 ml tube. Reactions were held at 37ºC for 1 hour and at 80ºC for 15 min. Sequencing reactions were performed with BigDye 3.1 system according to manufactures instructions (Applied Biosystems) and sequenced in a capillary electrophoresis automated sequencer (ABI310). Each sample was sequenced with forward and reverse primers. The consensus sequences were obtained by assembling the two complementary chromatograms in Sequencer 4.7 software.

Secondary structures of all sequences were obtained reconstructing by comparison via Pairwise Alignment (Bioedit) with previously reported structures in octocorals (Aguilar and Sánchez 2007). The sequences were then submitted with a few constrains and restrictions in MFOLD (Zuker 2003) at

a default temperature of 37ºC. The structure chosen was the one with the greater negative free energy but conserving the ring model known for ITS2. The obtained secondary structures were used to correct the alignment using the program 4SALE (Seibel et al. 2006). Phylogenetic analyses included maximum parsimony, maximum likelihood and Bayesian inference (see details in Grajales et al. 2007).

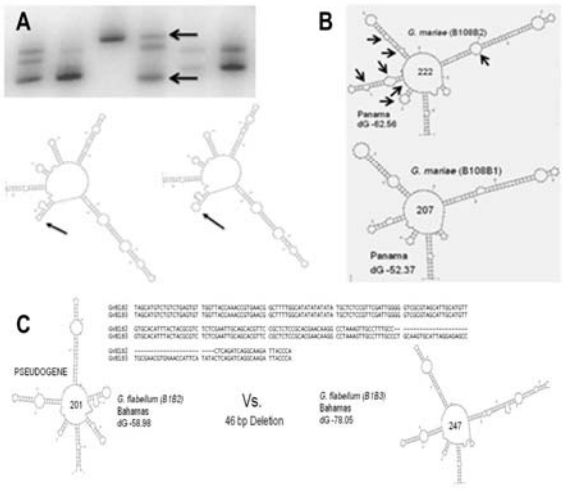

Figure 2: ITS2 predicted secondary structures from the intragenomic variants. A. Two different intragenomic ITS2 variants from an individual colony of *Pseudopterogorgia bipinnata* from Belize, corresponding to one mutation only. B. Two out of five different intragenomic ITS2 variants from an individual colony of *Gorgonia mariae*, including multiple differences. C. Diagnostic DGGE band (left) and a pseudogene (right) lacking most of the proximal helix in *G. flabellum*. Numbers refer to the nucleotide length and arrows point differences among structures.

Results

Gorgonia seafans exhibited a great deal of intragenomic variation as observed with multiple bands in DGGE (e.g., Fig. 1). There were different intragenomic patterns including species with a main "diagnostic" band, or dominant. Some individuals, mainly from *Gorgonia mariae,* did not have a dominant diagnostic band but up to five codominant bands (Fig. 1 inset). The intragenomic variation detected in DGGE gels, after reamplifying and sequencing, included the less amount of variation, a single nucleotide polymorphism (SNP), very common in colonies of *Psedopterogorgia bipinnata* (e.g., Fig. 2A), which was a good indicator that the method was reliable to separate all possible intragenomic variation. In addition, differences among intragenomic variants from the same individual could be highly significant with more than 15 INDELS and substitutions as in the case of *G. mariae* (e.g., Fig. 2B). The extreme case was observed in *G. flabellum* with more than 40 changes between two variants where one of them lacked the proximal helix (Fig. 2C), which should correspond to a pseudogene because it does not have the C2 processing site.

Preliminary phylogenetic analyses among the recovered intragenomic variants from DGGE gels were overall well supported by the three different phylogenetic approaches (Fig. 3). Paralyphyletic intragenomic variants were found in *Gorgonia mariae, P. bipinnata* and *G. flabellum*, although most *P. bipinnata* variants formed a monophyletic group. In contrast, some species such as *G. ventalina*, *P. acerosa,* and *P. rigida* had not variants or exhibited little divergence among intragenomic variants. The only pseudogene found in *G. flabellum* was located completely off *Gorgonia* and *Pseudopterogorgia* species near the outgroup. Although not all the intragenomic variants were successfully recovered from DGGE gels it was clear for *G. mariae* that its intragenomic variants were grouped with both *Pseudopterogorgia* and *Gorgonia* species within well supported nodes (Fig. 3).

Discussion

The study of ITS2 intragenomic variation provides additional compelling evidence for a likely hybrid origin of *Gorgonia mariae*, involving other *Gorgonia* and *Pseudoterogorgia* species as parental sources. Nonetheless, intragenomic variants from other *Gorgonia* and *Psedopterogorgia* species suggest that gene flow among seafans and sea whips might be more common than previously thought. Swarms of interbreeding species, known as a syngameon, have been proposed as a mechanism to quickly promote sympatric speciation via hybridization under adaptive radiation conditions (Seehausen 2004). The suggestive idea of the syngameon has been also proposed for scleractinian corals (Veron 1995, Kenyon 1997) and could explain the great diversity and phenotypic plasticity found in gorgonian corals. The alternative hypothesis about ITS2 intragenomic variation as incomplete lineage sorting of ancestral polymorphisms, might be rejected because ancestral polymorphisms, which should be older, might degenerate and turn into pseudogenes as seen with a corrupted RNA secondary structure. As mentioned before, pseudogenes were found only in *G. flabellum* but were infrequent and easy to detect. Therefore, functional ITS2 copies should be more recent as to prevent complete concerted evolution.

The preliminary phylogenetic hypothesis showed well-supported nodes suggesting multiple origins of *G. mariae* ITS2 intragenomic variants. *G. mariae* could acquire different ITS2 copies through the process known as introgressive hybridization (see review in Mallet 2005). Consequently, unless concerted evolution had occurred, hybridization processes leave

a footprint in the ITS2 generating mosaic copies from diverse parental genomes in *G. mariae*.

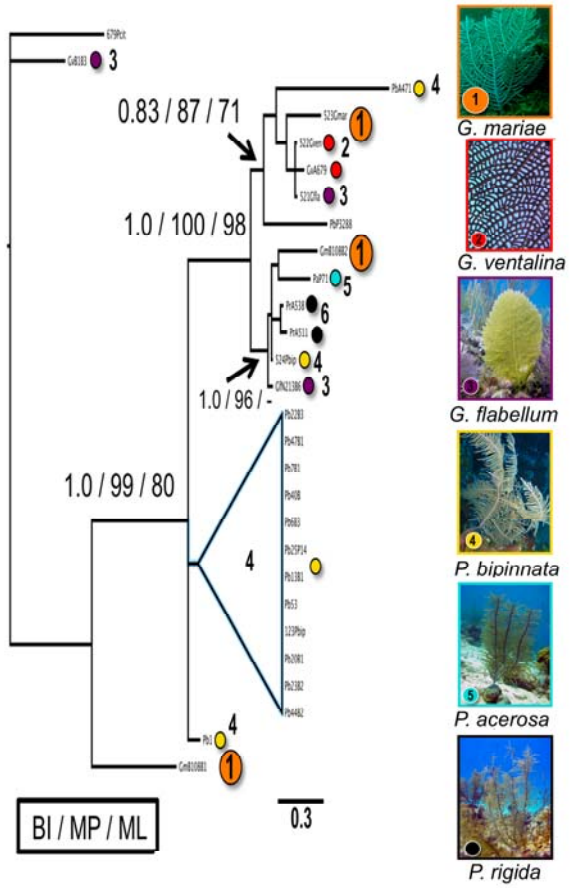

Figure 3: Preliminary phylogenetic results among ITS2 intragenomic variants in Caribbean *Gorgonia* and *Pseudopterogorgia* species. The tree is an optimum Maximum likelihood phylogram showing above node support from Bayesian Inference-BI / Maximum Parsimony-MP / Maximum Likelihood-ML. Scale bar 0.3 substitutions per site. Outgroup: *Pterogorgia citrina*.

Opportunely, scleractinian corals have provided straightforward evidence of introgressive hybridization particularly within species of *Acropora*, which have enlightened on the great potential for introgressive hybridization in sessile marine organisms with broadcast spawning. For instance, Odorico and Miller (1997) found consistent information in *Acropora's* ITSs with a reticulate evolution scenario. Van Oppen et al. (2001) examined diverse nuclear and mitochondrial DNA sequences concluding that paraphylly from most species could be explained by extensive introgressive hybridization and reticulate evolution. Likewise, Marquez et al. (2003) found the presence of ribosomal pseudogenes as a possible consequence of multiple hybridization events. Hybrid origin has also been proposed for soft corals species using ITS (McFadden and Hutchinson 2004). Nonetheless, Vollmer and Palumbi (2004) examined the multiple copies of the Caribbean *Acropora* species and concluded that there is no a proper way to evaluate if the intragenomic shared variation of genes such as ITS1 and ITS2 was the result of incomplete lineage sorting or recent hybridization processes. Yet ancestral polymorphisms should certainly retain more substitutions per site when compared with functional genes and for a ribosomal gene such as ITS2 that means purifying selection acting on secondary structural constraints (Cote and Peculis 2001) or concerted evolution mechanisms acting similarly (Liao et al. 2000, but see Nei and Rooney 2005 and Harpke et al. 2006). It is clear that the ITS2 is not a standard gene for reconstructing phylogenetic hypothesis (e.g., Harris and Crandall 2000) but it seems to retain clues from introgressive hybridization events, which should be examined in detail before reaching a robust conclusion. In conclusion, ITS2 is unfolding a different story of the diversification in octocorals thanks to the aid of techniques such as DGGE (see technological advantages over cloning in: Lajeunesse and Pinzon 2007) and RNA secondary structure prediction, which are techniques strongly recommended for the analysis of this kind of sequences.

Soft coral biodiversity and distribution in East Africa: Gradients, function and significance

M.H. Schleyer[1], Y. Benayahu[2]

1) Oceanographic Research Institute, PO Box 10712, Marine Parade, 4056 Durban, South Africa
2) Department of Zoology, Faculty of Life Science, Tel Aviv University, Tel Aviv 69978, Israel

Abstract. Soft corals (Octocorallia: Alcyonacea) constitute important reef benthos in East Africa, yet relatively little is known of their distributional gradients, function or significance. Integrated results of published surveys manifest interesting gradients in their diversity, abundance and apparent function. Reef disturbance may result in them becoming dominant, eliciting an alternative stable state in some coral communities. While certain tropical taxa attenuate from north to south, others attain their highest abundance at high latitude; the latter appears to be related to their ability to tolerate sedimentation and more swell-driven turbulence. Once established, soft corals appear to be persistent and long-lived. A long-term monitoring study has nevertheless revealed that they appear to be vulnerable to climate change.

Keywords: Soft corals, Alcyonacea, western Indian Ocean, biodiversity gradients

Introduction

Soft corals (Octocorallia: Alyonacea) have been studied on East African reefs at several localities over the last 15 years, including Tanzania (Ofwegen and Benayahu 1992), Mozambique (Benayahu & Schleyer 1996; Benayahu et al. 2002) and South Africa (Benayahu 1993; Benayahu & Schleyer 1995, 1996; Ofwegen and Schleyer 1997; Williams 2000; Williams and Little 2001). These studies have shown that soft corals are abundant in these countries, include descriptions of several new species, and list numerous new zoogeographical records for Tanzania (7°S), Mozambique (12-21°S) and the KwaZulu-Natal coast in South Africa (27.5°S).

The East African coast possesses a full spectrum of reef types, from fringing reefs off the mainland and islands in Mozambique and Tanzania (Hamilton and Brakel 1984; Wells 1988; Obura et al. 2000; Rodrigues et al. 2000) to the high-latitude marginal reefs of southern Africa (Schleyer 2000). Consideration is given here to gradients in the diversity and distribution of the soft corals and their underlying causes, aspects of which have received specific attention (Riegl 1995; Schleyer and Celliers 2003a, b; Schleyer et al. 2008).

The East African coastline under consideration in this study forms the boundary of the western Indian Ocean (WIO) and lies within the influence of the South Equatorial Current (SEC) and its daughter currents. These are generated when the SEC deflects off the northern tip of Madagascar and, in turn, encounters Africa at approximately 10ºS. Lutjeharms (2007) provides the most recent review of their complexity, the deflected currents in question being the East Madagascan, East African and Mozambique Currents. Further complex interactions give rise to the Somali and Agulhas Currents at equatorial and higher southern latitudes respectively.

Materials and Methods

Species lists providing the distributional patterns considered in this paper were derived from material collected in Tanzania; Pemba, Mozambique Island and the Quirimbas, Segundas and Bazaruto Archipelagos in Mozambique; and reefs off Sodwana Bay and Durban in South Africa.

Results and Discussion

Soft coral genera most commonly recorded on East African reefs are listed in Table 1. Less common genera have been omitted for brevity (see publications cited in the introduction for the full record). While some genera proved cosmopolitan, others were found only in the north or south. Most notable was *Cespitularia*, a genus that was locally abundant on reefs recovering from the 1998 El Nino Southern Oscillation-related bleaching in northern Mozambique (MHS pers. obs.; Fig. 1). Its extensive cover in these areas appeared to be opportunistic.

Endemism was high amongst genera in the south, examples listed in Table 1 being *Efflatounaria*, *Eleutherobia* and *Leptophyton*, endemic species of which were narrowly restricted to the South African east coast. This is probably attributable to the transitional nature, from tropical to temperate, of the sea off this coast.

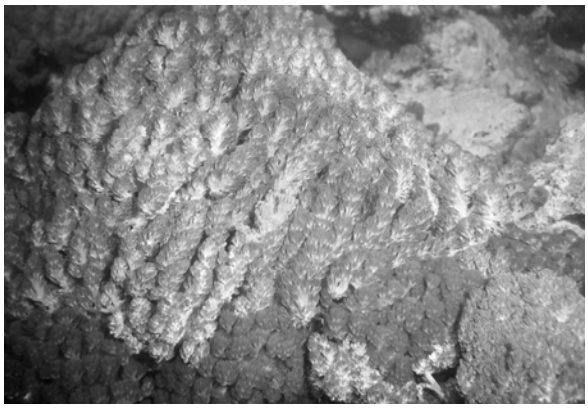

Figure 1. Bleached reef overgrown by extensive colonies of *Cespitularia*.

Table 1. Soft coral genera commonly recorded on East African reefs. TZ = Tanzania; MZ = Mozambique; ZA = South Africa. Grey shading denotes presence of genera and numerals the species, where known.

Stereonephthya Kükenthal, 1905				

Community data, when subjected to similarity analysis (Schleyer et al. in prep), revealed a gradient in abundance of soft corals, relative to the hard, from north to south (Table 2). The latter are dominant in the north but Alcyonacea become more successful in the south.

Table 2. Relative abundance (% cover) of soft and hard corals on East African reefs. TZ = Tanzania; MZ = Mozambique; ZA = South Africa.

Group	N MZ & STZ	S MZ	ZA
N (reefs)	7	3	8
Alcyonacea	6.6	18.7	31.3
Scleractinia	46.6	23.6	25.6

Fabricius (1995) described the slow-growing tenacity of the family Alcyoniidae, in contrast to faster-growing "fugitives" such as the Xeniidae and Nephtheidae. While the opportunistic nature of *Cespitularia* in East Africa has already been mentioned, *Lemnalia* and *Litophyton* were also evident in the north. Persistent alcyoniids, on the other hand, are notably abundant on South African reefs (Schleyer 2000; Schleyer and Celliers 2005; Celliers and Schleyer 2007; Schleyer et al. 2008) where *Sinularia* and *Lobophytum* form extensive carpets, particularly on surge-swept reef crests. This appears attributable to the frequency of large storm waves in the south (Fig. 2).

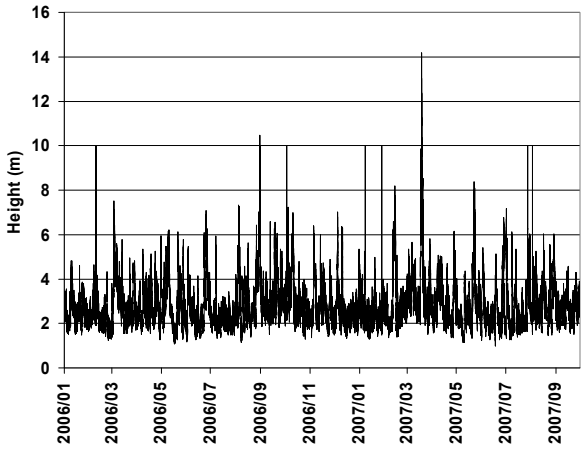

Figure 2. Maximum wave heights (m) recorded between January 2004 and December 2006, 100 km south of the South African coral reefs, portraying the frequency of storm waves in the area.
(Data courtesy of National Ports Authority – Richards Bay)

Persistent alcyonids gained a further competitive advantage during a spot outbreak of crown-of-thorns starfish (*Acanthaster planci*) where infested reef suffered a reduction in hard corals (Celliers and Schleyer 2006, 2007). Persistent soft corals became dominant in these areas, suggesting that their long-

term dominance causes the coral community to enter an alternative stable state.

High turbulence in the south mobilises sediment and a differential abundance of sediment-tolerant soft corals has been recorded on reef tops relative to the reef-sediment interface in South African coral communities (Table 3; Schleyer and Celliers 2003a). Their disposal of sediment is dependent on the turbulence that initially deposits it (Riegl 1995; Schleyer and Celliers 2003a).

Table 3. Relative abundance (% cover) of soft and hard corals in South African coral communities on reef tops relative to the reef-sediment interface (from Schleyer & Celliers 2003a).

	Reef-sediment interface	Reef tops
Alcyonacea	34.6 ± 3.8	31.3
Scleractinia	14.2 ± 4.0	25.6

Factors limiting coral reef development have been assessed by Kleypas et al. (1999), light and aragonite saturation being deemed constraining at high latitudes in the WIO. The resultant reduction of scleractinian competition would further account for the greater success of Alcyonacea in the south. The effects of climate change are anticipated to influence this (Schleyer and Celliers 2003b) and monitoring has revealed that the Alcyonacea have diminished in favour of the hard (Figure 3; Schleyer et al. 2008).

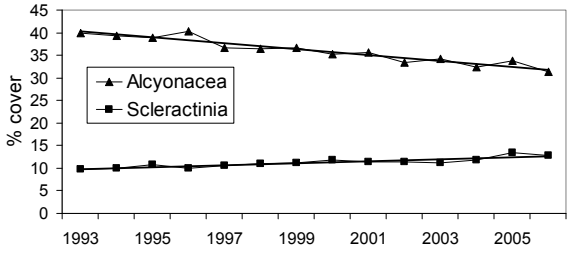

Figure 3. Overall changes in soft and hard coral cover measured at a long-term monitoring site in KwaZulu-Natal 1993-2006.

In conclusion, a number of parameters influence soft coral distribution on the East African coast. Some genera are limited to tropical or more temperate latitudes, with greater endemism at higher latitudes. Opportunism enables fast-growing pioneers to recolonise reef space in the tropics or, conversely, persistent slow-growers to attain dominance in the south. Reduced competition from Scleractinia due to climatic and environmental factors also facilitates the latter. Their proliferation is further promoted by the prevalence of heavy seas at higher latitudes as they are well-adapted to cope with the concomitant turbulence and sedimentation.

Acknowledgments

Collections and data considered in this paper were derived from work supported by a number of organisations; these are acknowledged in the literature cited. Presentation of the paper by MHS at the 11th Coral Reef Symposium was made possible by a grant from the National Research Foundation. Support for preparation of the manuscript came from the South African Association for Marine Biological Research and TRANSMAP (INCO-CT2004-510862), a project funded by the European Commission within the Sixth Framework Programme.

Recent Sightings of Longsnout Seahorse, *Hippocampus reidi* in the marine environment of St. Kitts, Lesser Antilles

R. Stimmelmayr[1,4], M. Sullivan[2], V. Latchman[3]

1) Ross University School of Veterinary Medicine, Box 334, Basseterre, St. Kitts
2) St. Kitts Reef Ecology Watch Group, St. Kitts
3) Kenneth's Dive Center, Basseterre, St. Kitts
4) Department of Veterinary Science, IAC, CRCD, University of Alaska Fairbanks, PO Box 99715

Abstract. Only two species of seahorses occur in the Caribbean: the Longsnout, *Hippocampus reidi,* and Lined Seahorse, *Hippocampus erectus*. Between 2007-8, several *H. reidi* specimens were repeatedly sighted at different shallow reef dive sites at St. Kitts. The reefs are mixed habitat with corals, sea grass beds, and sponges. Previous Longsnout seahorse sightings dating back to the early 90s have been inconsistent and restricted to only one of the sites. The recent frequent sightings and identification of several new reef sites could indicate an increase in the local seahorse population size. Further studies are needed to estimate the local seahorse population size and habitat characteristics.

Key words: seahorse population, Caribbean, *Hippocampus reidi, Syngnathus caribbaeus*, pipefish

Introduction

Seahorses (genus *Hippocampus*, family Syngnathidae) are distributed circumglobally in the marine environment. Despite their wide distribution, their life history characteristics (i.e. sparse and patchy distribution, low mobility/site fidelity, low fecundity and, lengthy parental care) make them vulnerable marine species to targeted catch (i.e. traditional Chinese medicine ingredient; aquarium trade) bycatch, and habitat degradation (Foster and Vincent 2004). Since 2004, the entire genus has been added to Appendix II of CITES, thus requiring international trade management by the 166 signatory nations. In the Caribbean, only two species of seahorses occur, namely the Longsnout (*Hippocampus reidi)* and Lined Seahorse, (*Hippocampus erectus)*. The Lined Seahorse is currently listed by the IUCN as a vulnerable species. General information on the abundance of Longsnout seahorse is lacking, and the species has been categorized as data deficient, indicating a need for further studies. *H. reidi* and *H. erectus* are both species used in traditional Chinese medicine.

Material and Methods

St. Kitts (17° 9' N 62° 45' W) is a small Caribbean island of volcanic origin that is part of the Lesser Antilles chain. As part of a large scale local marine ecosystem survey project, data on seahorse/pipefish species, site location, depth, number of specimens, and associated marine habitat were collected during roving diver/snorkel surveys (2006-2008). When feasible, specimens were photo documented. In situ, visual identification of species was based on gross morphological distinct features (ie. color patterns, snout length, body shape, and presence/absence of skin appendages). We are using the taxonomy of Laurie et al. 1999.

Figure 1. Longsnout seahorse at Monkey Shoals

Results

Specific location data, and color patterns for all seahorse sightings are summarized in Table 1. The habitats associated with the sighted seahorses can be classified as mixed habitat with coral gardens, gorgonians, and intermittent sea grass beds. Only one male of 13 cm size and with a large brood pouch was observed. No *H. erectus* specimens were sighted despite the previous confirmed distribution of the

lined seahorse in St. Kitts waters. Longsnout specimens were always associated with holdfast structures such as sea grass, gorgonians, and black corals. In addition to the Longsnout seahorse, individual Caribbean pipefish (*Syngnathus caribbaeus*) specimens were repeatedly sighted in Spring 2008 at South Friars (n=4) and once at Monkey Shoals. The specimens found at South Friars were in shallow water (approx. 6 feet) and occupied shallow, slender rock crevices filled with sand. The specimen found at Monkey Shoals (approx. 25 feet) was found hiding among sea whips.

New Sites	Old Sites
Monkey Shoals *September 2007*: individual: brown *January 2008*: 2 individuals: 1 brown, 1 dark maroon slender male with distinct brood pouch; approx. height 13-17 cm; 1 smaller individual; *May 2008*: individual: brown; *August 2008*: 2 individuals: 1 brown, 1 black; approx. height 13 cm.	**Brimstone Reef** *April 2007*: individual: yellow coloration with white bands along tail; hiding in a sea plume; consistent seahorse sighting over the last several years
Challenger Reef *March 2008*: individual	**Paradise Reef** *June/July 1993*: individual: white blotches along tail
River Taw *September 2007:* individual: very light brown/yellowish	

Table 1: Listing of historic and current seahorse sightings in St. Kitts

Discussion

While Lourie et al. (2004) list *H. erectus* with a distribution for St. Kitts and Nevis, our study demonstrates the presence of *H. reidi* at St. Kitts, but not that of *H. erectus*. Predominant coloration of specimens in St. Kitts was black/brown to orange/maroon, similar to specimens in St. Lucia (Humann and Loach 2004); only one specimen showed yellow coloration with white-brown bands/saddles along tail, similar to a specimen from Little Cayman (Humann and Loach 2004) and Longsnout seahorse specimens identified at Saba (Saba Divers pers. comm.. 2007). Unpublished sightings of the Longsnout seahorse at Brimstone Reef are dating back to the early 1990s but sightings have been inconsistent at this site. The home range of the Longsnout seahorse is small with a reported size of 13.3 m^2 for females and 3.5 m^2 for males (Dauwe 1992), and during breeding season they are thought to show site fidelity. Despite the small home range, only one pair has so far been observed (Table 1) and one individuals had a large brood pouch. The male specimen height was estimated 13-17 cm. Maximum adult height for *H. reidi* is reported at 17.5 cm (Laurie et al. 1999), and 8 cm height at first maturity (Vari 1982). Recorded mean range densities for *H. reidi* in Brazil are 0-51 m^2 and 0–0.006 m^2 (Dias & Ross 2003). Densities in St. Kitts are in the lower density range.

Caribbean pipefish (*Syngnathus caribbaeus*) specimens have previously not been reported from St. Kitts; however their reported Caribbean distribution includes the Greater and Lesser Antilles (Fishbase; Humann and Deloach 2004) where they inhabit weedy or sandy bottoms of shallow inshore waters.

The recent frequent sightings and identification of several new reef sites with Longsnout seahorses could indicate that St. Kitts has a viable and potentially expanding *H. reidi* population. However, St. Kitts, and in particular the Southeast Peninsula, is currently experiencing accelerated development that may impact near-shore marine water quality and resources through construction-related sediment run-off and intensified water tourism (i.e. boating, jet-skiing, snorkeling, diving, marine mammal park). Further studies are urgently needed to better define the current seahorse population size/density in the waters of St. Kitts.

3) University of Alaska Fairbanks, CRCD, Fairbanks, Alaska

Abstract. Nine species of Cymothoid isopods of the genera *Anilocra* spp. selectively associate with specific West Indian fish species and are location specific. *Anilocra* infestation negatively impacts fish productivity and health. As part of a large scale marine ecosystem survey project of the marine environment (2006-2008), isopod parasitism as a potentially useful marine ecosystem health indicator was monitored during roving diver/snorkel fish species surveys. We report for the first time for St. Kitts the presence of *Anilocra chromis* on brown chromis (*Chromis multilineatus*), but not Blue chromis (*C. cyaneus*), and *Anilocra haemuli* on French grunt (*Haemulon flavolineatum*), Smallmouth grunt (*H. chrysargyum*), Caesar grunt (*H. carbonarium*), and Tomtate grunt (*H. aurolineatum*). Our data supports the previously reported geographic specificity of *Anilocra chromis* infection whereby only Blue or Brown chromis, but never both, are affected within one locality.

Key words: Cymothoid isopods, ectoparasites, coral reef fish, West Indies

Introduction

Cymothoid isopods are permanent ectoparasites of fish. They mostly occur in the near shore coastal marine environment. Cymothoid parasites are protondrous hermaphrodites that attach to the fish surface, mostly around the head region. *Anilocra* infestation is known to impact breeding success, interfere with swimming dynamics, decrease fish size, reduce erythrocyte number, and is known to cause lesions in the host ranging from localized tissue inflammation to underlying bone deformities (Bunkley-Williams and Williams 1998; Adlard and Lester 1995). Nine species of cymothoid isopods (pathogenic parasite) of the genera *Anilocra* spp**.** selectively associate with specific West Indian fish species and are host and site-specific (Bunkley-Williams and Williams 1981).

Material and Methods

St. Kitts (17° 9' N 62° 45' W) is a small Caribbean island of volcanic origin that is part of the Lesser Antilles chain. As part of a large-scale local marine ecosystem survey project, data on cymothoid isopods species, site location, attachment site, number of isopods per fish, and associated marine habitat were collected during roving diver (n=80) /snorkel surveys (n=300) in 2006-2008). When feasible, fish specimens with isopods were photo documented.

Results

In 2007 and 2008, Anilocra chromis on Brown chromis (*Chromis multilineatus*) and *Anilocra haemuli* specimens on French grunts, Smallmouth grunts (*H. chrysargyum*), and Caesar grunts (*H. carbonarium*) were identified during daytime at shallow (< 30 feet) to deep reef sites (> 50 < 100 feet) along the Caribbean side of the island. The associated habitats can be classified as mixed habitat with rubble, coral gardens, gorgonians, and intermittent sea grass beds. Median (min-max) number of isopods observed on coral reef fishes in the marine environment of St. Kitts by survey location is summarized in Table 1.

Anilocra chromis were observed at 93% of the dive sites and at 55% of the snorkel sites. *Anilocra haemuli* on French grunts were observed at 14% of the dive sites and at 77% of the snorkel sites. At none of the dive sites did Caesar and Smallmouth grunts have isopods; however, isopods were present respectively at 22% and 11% of the snorkel sites. Tomtate grunts were affected on 7% of the dive sites and 11% of the snorkel sites. No *Anilocra haemuli* were observed at any of the surveyed sites on other suitable fish hosts such as Coney (*Cephalopholis fulva*), Red hind (*Epinephelus guttatus*), and Graysby (*Cephalopholis cruentatus*). For all fish affected with isopods, the host location of isopods was beneath the eye of host. The observed isopods were of mature size and featured prominently on the face of the hosts. Bilateral isopod association was less common, but not infrequent. We never observed more than one isopod per side.

Discussion

We report for the first time for St. Kitts the presence of *Anilocra chromis* (Williams and Williams 1981) on brown chromis, but not blue chromis (*Chromis cyaneus*), and *Anilocra haemuli* on French grunts, Smallmouth grunts, Caesar grunts, and Tomtate grunts. Previous reported distribution for *Anilocra chromis* on brown chromis has included the northeastern West Indies, namely Puerto Rico, Mona Island, and the British and US Virgin Islands. Blue chromis have been affected in the Bahamas and Dominican Republic (Williams and Williams 1981). Our data supports the previously reported geographic specificity of *Anilocra chromis* infection whereby only blue or brown chromis but never both are affected within one locality (Williams and Williams 1981; 1982). Isopod attachment as previously described by Bunkley-Williams and Williams (1981) for *Anilocra chromis* and *A. haemuli* is beneath the eye of host (Fig. 1). Affected grunts appeared depressed. We did not measure body size, but no obvious size differences were apparent in affected versus unaffected hosts. Recent work with cardinal fish suggests that *Anilocra* parasitism has significant energetic consequences for the host (Ostlund-Nilsson et al 2005).

Our data indicates subtle geographic differences in cymothoid isopods presence in the marine environment of St. Kitts. *Anilocra chromis* were mostly observed at the dive sites. *Chromis* are preferentially found between 35-80 feet. Thus our results probably reflect their habitat choices. We also observed distinct differences for *Anilocra haemuli* between dive and snorkel sites despite the commonness of grunts at these different depths. In addition, although other fish species (i.e. Coney, Red hind, Graysby) known to be parasitized by *A. haemuli* are present at the snorkel and dive sites, only grunts were affected.

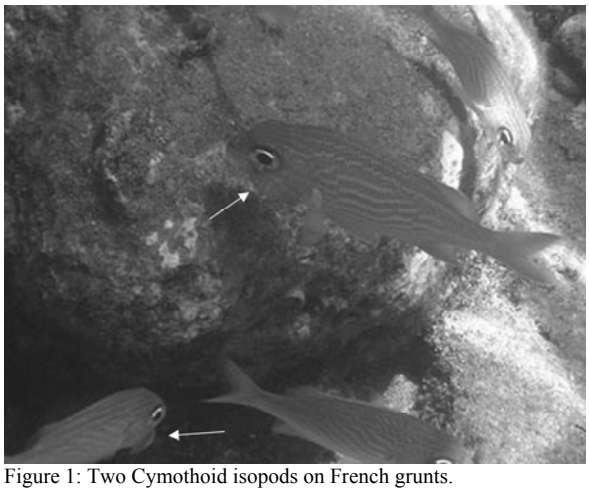

Figure 1: Two Cymothoid isopods on French grunts.

We do not know what environmental and ecological factors (i.e. fish aggregates versus solitary fish, seawater temperature, ocean currents, algae, low light levels, cleaner density) are contributing to the observed geographic differences in cymothoid isopod parasitism. Our preliminary data suggests that there is no difference in presence of cleaner fish between the near shore versus deep sites (Sullivan and Stimmelmayr unpubl. data). Increased fecundity of *Anilocra* spp. in the Mediterranean is linked to warmer water temperature during the summer months (Varvarigos 2003). We did not measure water temperature; however, based on long-term local marine stakeholder observations, seasonal local seawater temperature increases have been occurring earlier and lasting longer. Further studies are needed, including water quality measurements, nutrient content, and temperature monitoring to get a better understanding of the ecological constraints affecting cymothoid isopods in the tropical marine environment. *Anilocra* spp. infestation has a potential to be a useful

marine ecosystem health indicator in a changing environment.

Acknowledgements We thank S. Fitzharris for additional photos and isopod observations.

Abstract. As part of the CSIRO Wealth from Oceans Ningaloo Collaborative Cluster programme currently underway in Western Australia, this study aims to examine lagoonal habitats and biodiversity within Ningaloo Reef. Key habitat types were identified using information from hyperspectral remote sensing and were used to develop a stratified sampling approach. Two focal areas were selected, based on sanctuary zones within Ningaloo Marine Park: Osprey Bay and Coral Bay in the north and south respectively. A nested quadrat sampling regime was used to attempt to link field-collected data with remotely-sensed data, collected at different scales. Preliminary results confirm that northern sections of Ningaloo Reef differ greatly from the south, with a greater diversity of habitats present in the broader lagoons in the south. Greater areas of coral are found close inshore and across the entire reef at the southern location, compared with the northern section, which has a broad expanse of sand and limestone pavement before grading to corals further offshore (back-reef and reef-crest). These differences in habitat may have implications for the overall biodiversity of the two locations and more broadly along the reef.

Key words: Biodiversity, Ningaloo Reef, habitats, hyperspectral imagery, lagoon.

Introduction

Habitats and biodiversity of lagoonal areas at Ningaloo Reef, Western Australia are currently being studied as part of the CSIRO Wealth from Oceans Ningaloo Collaborative Cluster programme. The aim of the Cluster is to integrate knowledge of reef use and socioeconomics with biodiversity and habitat maps to deliver a management strategy for the Marine Park. This study will deliver high-resolution spatial data on the habitats of the marine and coastal areas of the Ningaloo Marine Park and an understanding of how biophysical characteristics of the ecosystem relate to Ningaloo's biodiversity.

Ningaloo Marine Park extends for some 280 km along the northwest Australian coastline. The unusual circumstances of the poleward-flowing Leeuwin Current, low rainfall and low runoff (resulting in very clear waters), remoteness and strong management regime have resulted in a highly diverse, high-latitude coral reef system in relatively undisturbed condition (Cassata and Collins 2008). The region's low rainfall and low runoff (resulting in very clear waters) makes aerial photography an ideal tool to examine coastal geomorphology and habitat structure. High-resolution hyperspectral aerial photography is being used to provide detailed habitat maps for the entire Ningaloo Marine Park.

The remoteness of this region means that much of the reef is difficult to access. Existing habitat maps have been derived from in-water surveys that have focused on small sections of the reef (Bancroft and Sheridan 2000). The oceanography of Ningaloo Reef is dominated by the southward-flowing Leeuwin Current, which is forced offshore around Point Cloates by the northward-flowing Ningaloo Current (Taylor and Pearce 1999). This effectively divides the Ningaloo Reef into two distinct zones, with the northern zone under stronger influence of the Leeuwin Current than the south, resulting in a potentially higher proportion of tropical species in the northern section of the reef.

Most of the major taxonomic groups have received little or no attention at Ningaloo; biodiversity surveys will especially target the macroalgae, the Cnidaria other than hard corals and the sponges. These groups have had very little work done on them despite the fact that they are critical components of coral reef community structure. This component of the Ningaloo Wealth from Oceans Collaborative Cluster is combining biodiversity surveys and remote sensing

data to develop detailed habitat maps of the entire Ningaloo Marine Park. This paper presents preliminary data from the nested quadrat sampling programme.

Material and Methods

Key habitat types were identified using information from hyperspectral remote sensing and were used to develop a stratified sampling approach. Study areas were also selected to encompass differences caused by current flows along the Ningaloo Reef. The Coral Bay region in the south and Yardie Creek/Osprey Bay in the north have been selected as representative of the northern and southern geographic regions of the reef (Figure 1). Four habitat sub-types were sampled at each location: reef-crest, back-reef, lagoon and inner reef-flat. This paper describes preliminary data from nearshore sampling.

Sampling strategies included monitoring benthic habitat types along transects, nested quadrats to match up with the pixel size obtained by remote sensing, and transects to quantify numbers of key invertebrate species (holothurians, tridacnid clams, and the corallivorous snail, *Drupella*).

The nested quadrat design is intended to provide a link between the remotely sensed data (3.5 m pixel size) and diver-monitored benthic sampling. 9 x 9 m quadrats were marked out underwater and divided into nine 3 x 3 m sub-quadrats (Figure 2) (McDonald 2007). Estimates of benthic cover were obtained for the large quadrat and sub-quadrats using modifications of the categories developed for the Australian Institute of Marine Science long-term benthic monitoring programme (English et al. 2004). A minimum of three nested quadrats were sampled for each sub-region; further sampling is currently underway.

Results

Data presented here include preliminary nested quadrat samples from lagoon areas within Osprey Bay, Yardie Creek and Five Finger lagoon, which is within the Coral Bay region. All sites showed a predominance of sand, macroalgae and rubble as expected; the key difference observed was a significant level of soft coral cover at the Osprey Bay site (Figure 3). The pie charts represent the major benthic categories within the lagoonal areas at the three study sites (mean of 5, 6 and 3 samples at Osprey Bay, Yardie Creek and Five Finger Lagoon respectively). Osprey Lagoon showed a greater proportion of sandy substrate although the diversity of substrates was greater than the other sites. The dominant categories have been highlighted in each chart for clarity.

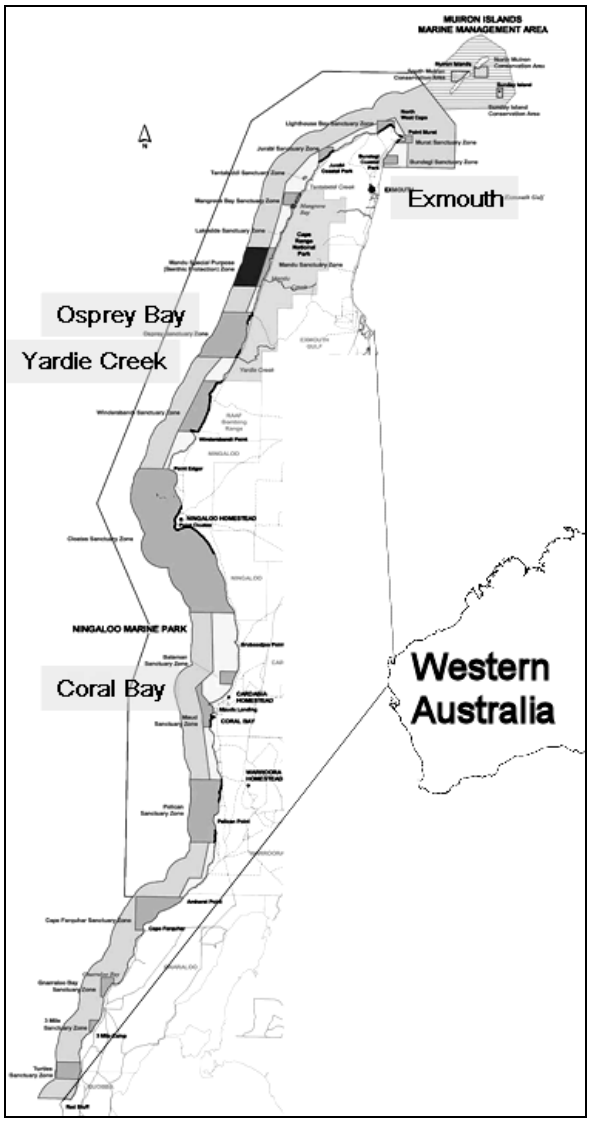

Figure 1: Ningaloo Marine Park in NW Australia. The Park boundary is indicated as State waters (to 3 nautical miles) and Australian Commonwealth waters (to 12 nautical miles). The specific study sites, Coral Bay, Yardie Creek and Osprey Bay are marked.

Discussion

The biodiversity sampling associated with the CSIRO Wealth from Oceans Ningaloo Collaborative Cluster programme has two primary purposes: firstly, to validate the hyperspectral data used to develop detailed habitat maps of the Ningaloo Marine Park; and secondly, to help fill gaps in the biodiversity knowledge of the Ningaloo Reef system. The data collected by the process described in this paper provides excellent validation for the hyperspectral remote sensing programme and good spatial determination of benthic habitat categories. Preliminary habitat classification was used to identify possible field sampling targets and this provides a

powerful mechanism for obtaining both confirmation of the classification process but also the relevance of the benthic categories being used in water. Additional validation sampling has included cross-reef transects, point sampling and diver-towed in-water GPS records of identifiable features.

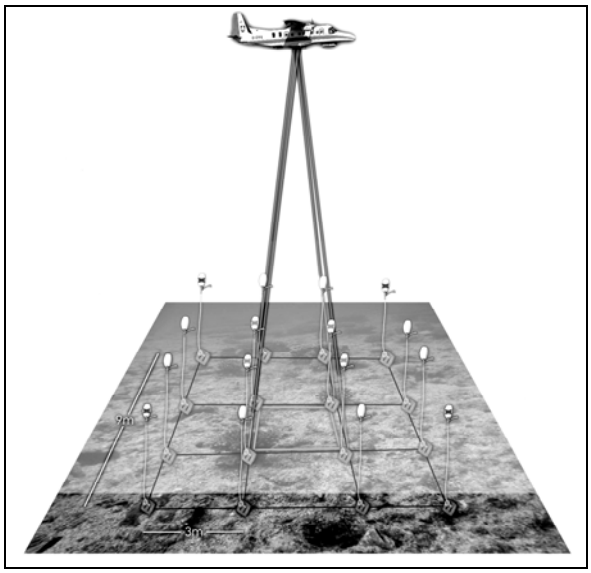

Figure 2: Schematic of nested quadrat design. Large quadrats are 9 x 9 m, sub-divided into nine 3 x 3 m sub-quadrats, approximately matching the aerial photography pixel size of 3.5 m.

Studies of oceanographic processes offshore of Ningaloo Reef indicate an interruption to the flow of the major local currents at Point Cloates, located approximately halfway along the length of the reef. At this point the southward flowing Leeuwin Current is forced offshore by the Ningaloo counter-current, which loops back as an eddy (Taylor and Pearce 1999). This interruption of the warm, nutrient-poor Leeuwin Current has considerable implications for trophic relationships on the reef. One of the preliminary observations that can be made from the data presented in this paper is the difference in major taxonomic and substrate categories identified at the sample sites. While sandy substrates predominate at all three sites (as expected from lagoon samples), there is a significant component of soft corals present in the Osprey Lagoon samples which does not occur further south. Conversely, the southern site is dominated by macroalgae, coralline algae and tabulate *Acropora*. It is anticipated that further samples from other sectors of the reef will shed more light on these differences in taxonomic categories and benthic habitats.

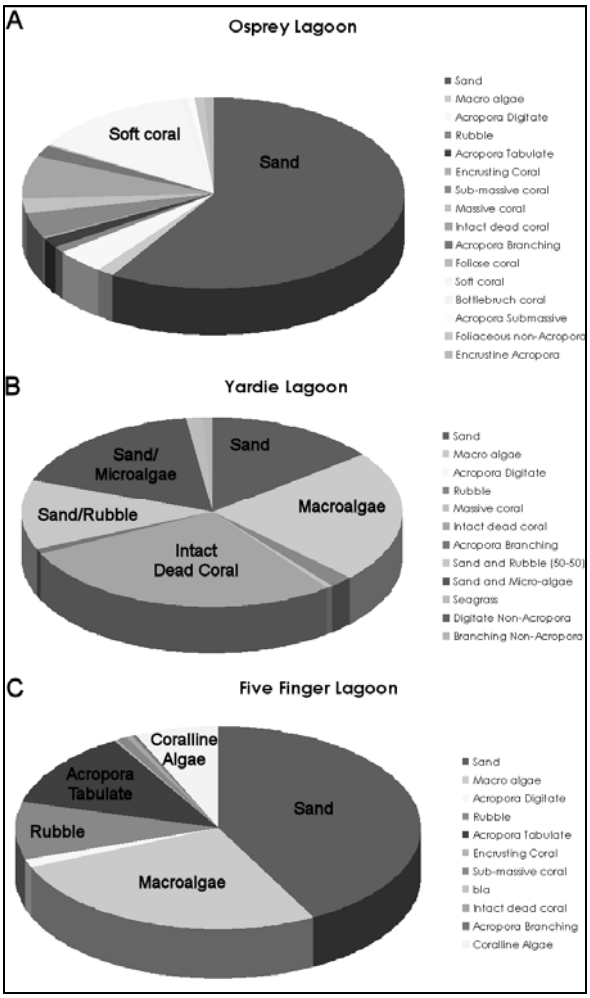

Figure 3: Major benthic categories identified from benthic nested quadrat surveys at A) Osprey Lagoon (n = 5), B) Yardie Creek Lagoon (n = 6) and C) Five Finger Lagoon (n = 3). Dominant categories have been labeled for clarity.

When combined with bathymetric data also derived from the hyperspectral aerial photography it is anticipated the habitat maps generated from this project will provide a framework for studies examining biodiversity patterns and factors influencing the distribution of significant wildlife aggregations in the region. The data generated by this study will be integrated with several other biodiversity studies currently underway in the Ningaloo region and will help to inform management decisions about the Ningaloo Marine Park.

Coral systematics inferred from the gene galaxin: Exploring phylogenetic relationships using a putative determinant of skeletal morphology

H.H. Wirshing and A.C. Baker

Division of Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science, University of Miami, 4600 Rickenbacker Causeway, Miami, FL 33149, USA

Abstract. Molecular phylogenies and morphological datasets may not entirely agree, and often fail to accurately reconcile many phylogenetic uncertainties. In corals, one way of resolving this disagreement is to complement the existing sets of genetic markers by identifying and analyzing genes directly responsible for generating morphology. Since traditional taxonomy in corals has been dependent almost entirely on their biomineralized skeletal morphology, the use of genes controlling these processes may help identify cases where morphological taxonomy has led to different conclusions about scleractinian evolution. To test this approach, we used the cDNA sequence of the protein galaxin, isolated from the organic matrix of *Galaxea fascicularis*, to amplify a ~363bp DNA fragment from 18 scleractinian species in 8 genera. Translated amino acid sequences revealed minimal within-species sequence variation within *G. fascicularis* collected from 5 different geographic locations. Phylogenetic reconstruction found three well-supported clades, one containing members of the Acroporidae (Complexa), one comprising members of the Oculinidae and Euphyllidae (Complexa), and one comprised of genera from the Siderastreidae, Faviidae and Agariciidae (Complexa and Robusta). These preliminary results illustrate an approach which may help better understand the morphological variation upon which traditional taxonomy has been based.

Key words: coral, systematics, phylogenetics, taxonomy, galaxin, DNA, scleractinia.

Introduction

Uncertainties in scleractinian taxonomy are rooted in the inability to accurately decipher morphological homologies. Formal taxonomic descriptions of scleractinians have utilized a variety of morphological features ranging from septal microstructure (Wells 1956) to corallite and colony morphology (Veron 1995, 2000) to create taxonomic classifications that imply the diversification of the group. Molecular DNA approaches provide an opportunity to independently test these taxonomic hypotheses. Over the last ~12 years, the systematic relationships of scleractinian corals have been challenged by phylogenetic reconstructions based on nuclear and mitochondrial DNA (Romano and Palumbi 1996, Chen et al. 2002, Fukami et al. 2004, 2008). These studies recovered phylogenies that do not agree with many of the traditional taxonomic assignments within the Scleractinia, particularly at the subordinal and family levels.

At least two major themes have arisen concerning the evolution of the scleractinia based on DNA evidence. The first theme asserts the scleractinian lineage is comprised of two major clades – the "robust" and "complex" corals (Romano and Palumbi 1996, 2000, Chen et al. 2003). The "robust" corals consist of heavily calcified corals as a result of a dense construction of their corallite walls (e.g. septothecal or parathecal). In contrast, the "complex" corals contain many corals that build more lightly calcified skeletons due to a relatively porous skeletal assembly of their corallite walls (e.g. synapticulothecal). A second theme states that there is pervasive morphological convergence of many Atlantic and Pacific scleractinian genera (Fukami et al. 2004, 2008). Many Atlantic genera are more closely related to each other than they are to their Pacific congeners and *vice versa*. This implies that many Atlantic and Pacific lineages each experienced their own intra-basin radiations and converged on similar morphological features, detected by examination of their corallite wall architecture.

Other studies have narrowed the link between molecular phylogenies and the biomineralization patterns of corallite microstructures in order to determine homology among taxonomically questionable groups. Benzoni et al. (2007) examined septal micro-features of the centers of calcification of *Psammocora* spp. of debatable taxonomic affinity. Cuif et al. (2003) demonstrated that the growing

edges and numerous granules and spines related to septal growth, once considered unimportant ornaments, are important features of the initial skeletal framework and contain valuable phylogenetic information.

All of these studies assume that the molecular markers used can serve as accurate proxies for the evolution of their taxonomic characters, and can thus be tied to morphological changes in those taxa. In many cases, this assumption has been validated and accurate corroborations between molecular phylogenies and coral morphologies have elucidated many novel evolutionary relationships (e.g. Romano and Palumbi 1996, Fukami et al 2004, 2008). However, many systematic relationships still remain unresolved because of the inability of the molecular markers used to unequivocally resolve all of the systematic uncertainties within the Scleractinia. An approach to solving this problem is to augment the current regime of scleractinian molecular markers by identifying and analyzing genes directly responsible for generating morphology. Unlike most organisms (whose taxonomy is based on many phenotypic characteristics that collectively can not be pinned to a single genetic function), coral taxonomy is almost exclusively based on their skeletal (calcium carbonate) morphology that is genetically controlled by the biomineralizing machinery of their genomes. This characteristic offers the possibility to utilize these molecular "drivers" (genes responsible for calcification/morphology) in concert with existing molecular markers in order to potentially identify areas where morphological taxonomy may have led to different conclusions concerning scleractinian evolution.

This study represents an initial look at the utility of the gene galaxin, a region that encodes for a protein isolated from the organic matrix (a consortium of proteins that forms the scaffolding for biomineralized structures) of the coral *Galaxea fascicularis* (Fukuda et al. 2003), for phylogenetic reconstruction.

Material and Methods

Samples were collected by coring a 1cm x 1cm fragment from individual coral colonies. Tissue and skeletal material were stored in either 95% EtOH or saline DMSO. Total genomic DNA was extracted by established protocols (see Rowan and Powers 1991). Primers Gal16(F) 5'-GGAGCTACCCAGTTATGCTG-3' and Gal13(R) 5'-TATGCTAGCCCAGCACAGGAT-3' were designed from the published cDNA sequence of the gene galaxin (Fukuda et al. 2003) and were used to amplify all *Galaxea* spp., *Euphyllia* spp., *Diploria labyrithiformis*, *Pachyseris speciosa*, and *Acorpora cervicornis* samples. Primer Gal13mc(R) 5'-TATGCAAGTCCTGCGCAAGAT-3', designed from the galaxin sequence of *Montipora capitata* (Accesion # EU022118) was used with primer Gal16(F) (see above) to amplify all *Montipora* spp., *Siderastrea* spp., and *Solenastrea bournoni* (Table 1). PCR (polymerase chain reaction) was conducted using Promega GoTaq® DNA polymerase and provided buffers. Thermocycler reaction parameters were: initial denaturing step at 94°C for 3 min., followed by at total of 35 rounds of 94°C for 1min., 50°C for 1min., and 74°C for 1min. A final extension step of 72°C for 7min completed the reaction. PCR amplifications were confirmed by running products on 2% agarose gels. All successful amplifications were directly sequenced on an ABI 3730 sequencer and forward and reverse sequence contigs were edited with the software ContigExpress in Vector NTI Advance™ 10 (www.Invitrogen.com).

DNA sequences were translated into amino acid sequences using GeneDoc (Nicholas and Nicholas 1997) and aligned using MUSCLE (Multiple Sequence Comparison by Log-Expectation) (Edgar 2004). ProtTest (Abascal et al. 2005) was used to determine the model of amino acid substitution that best fit the alignment. Phylogenetic reconstruction was performed using Bayesian Maximum Likelihood (MB) in MrBayes v3.1.2 (Huelsenbeck and Ronquist 2001). Tree space was explored using 4 Markov chains for 1,000,000 generations with trees sampled every 100 generations. Posterior probabilities were calculated by setting the "burn-in" to 2500 (25% of

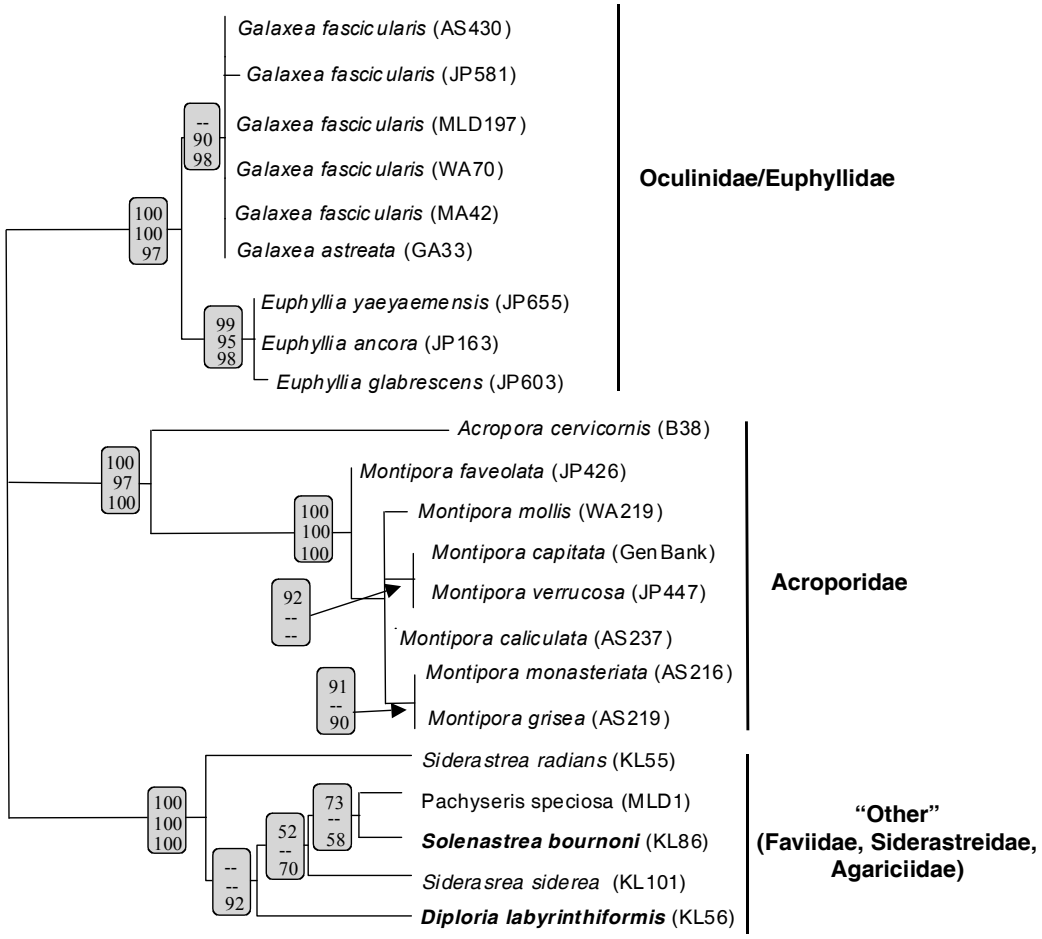

Figure 1: A cladogram depicting relationships recovered by Bayesian Maximum Likelihood (MB), Maximum Parsimony (MP), and Minimum Evolution (ME). Posterior probabilities (MB) and bootstrap values for MP and ME >50 for each node are shown in boxes from top to bottom, respectively. Vertical lines on right highlight clades that correspond to familial groups recovered (Oculinidae/Euphyllidae and Acroporidae) or where relationships were uncertain ("other"). "Robust" corals are in bold. "Complex" corals are in normal font. "--" indicates node <50 or not following branching topology for that method.

sampled trees), and values were generated from the remaining 7500 trees. Maximum Parsimony (MP), with branch swapping set to TBR (tree bisection-reconnection) and starting trees gained by stepwise addition (random), and Minimum Evolution (ME) (default parameters for amino acid sequences) were performed using PAUP* v4.0b10 (Swofford 2002). 1000 bootstrap replicates were performed for each method.

An appropriate outgroup to root the phylogenetic trees was not available, as the gene galaxin has not been found outside the Scleractinia. As a result, all trees were rooted with midpoint rooting in PAUP*. MrBayes does not allow for midpoint rooting, so no root was used.

Results

The sequenced PCR fragments, after editing, were 363bp in length except for the *Monitpora* spp. and *Acropora cervicornis*, which were 357bp. Translated amino acid sequences were, thus, 121 and 119 amino acids in length. Two indels, of one amino acid each, were located at the 9th and 37th positions in the alignment (data not shown). ProtTest found the model Dayhoff + G to best fit the alignment with both Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) frameworks.

All three methods of phylogenetic reconstruction found three major clades with high statistical support – *Galaxea* spp.-*Euphyllia* spp., *Montipora* spp.-*A. cervicornis*, and *Siderastrea* spp.-*Pachyseris speciosa*-*Solenastrea bournoni*-*Diploria labyrinthiformis* (Fig. 1). The phylogenetic relationship among them was unresolved. The *Montipora* spp.-*A. cervicornis* clade corresponds to generic memberships within the family Acroporidae. The *Galaxea* spp.-*Euphyllia* spp. clade unites genera from the families Oculinidae and Euphyllidae. And a third clade joins species from four genera and three families (Faviidae-Siderastreidae-Agariciidae).

The *G. fascicularis* from five different geographic locations (Table 1) were invariant in their amino acid sequences except for one change (threonine to serine) in the Japan individual at position 64 in the alignment (data not shown). Among congeners, the relationships among the three species of *Euphyllia* were unresolved. The *Montipora* spp. did, however, show some structuring, although statistical support was inconsistent among all phylogenetic reconstruction methods. For example, *M. capitata* and *M. verrucosa* grouped as supported sister species with MB (92) only, and *M. monasteriata* and *M. grisea* fromed a clade supported by MB (91) and ME (90) (Fig. 1).

The "Faviidae-Siderastreidae-Agariciidae" clade contained unexpected relationships, most of which were not supported by high bootstraps values or posterior probabilities (Fig. 1). For example, *S. radians* and *S. siderea,* two well-known morphological sister species, did not group monophyletically.

Discussion

The organic matrix of corals is a consortium of proteins that is intimately associated with the calcification process in many organisms including corals (Simkiss and Wilbur 1989). Cuif and Dauphin (2005) describe the calcification procedure in corals as a biochemically driven process where genetically controlled coral fibers, of which sulfated acidic proteoglycans are likely to play a significant role, guide calcification in repeated cycles. Similarly, Meibom et al. (2008) state that the morphology of the coral skeleton is related to the genetically defined positions and distributions of their centers of calcification. It is, therefore, plausible to assume that much of the evolutionary history of the coral skeleton, including convergences, may be found in the genes involved in the biomineralization process of the coral skeleton. It is still unknown, however, to what degree (or if at all) organic matrix proteins, including galaxin, play in that process.

Here, we use only ~40% of the organic matrix protein sequence of galaxin across several coral taxa. We utilized translated amino acid sequences in order to examine any variation in the protein sequence that may account for morphological differences in coral skeletons. Our phylogenetic reconstruction employed only a small set of scleractinian species due to the inability to successfully amplify galaxin across divergent taxonomic groups. Our tree, however, recovered many traditional taxonomic groupings based on morphology as well as groupings based on studies using other DNA markers. For example, the *Montipora* spp.-*A. cervicornis* clade recovered corroborates the well-established morphological relationship between these two genera (e.g. Wells 1956), both of which are placed within the family Acroporidae. This relationship has also been verified by molecular phylogenies using both nuclear and mitochondrial DNA (Romano and Palumbi 1996, Chen et al. 2002, Fukami et al. 2008). Although not well supported by all of the reconstruction methodologies used, the pairing of four *Montipora* spp. (*M. capitata* with *M. verrucosa* and *M. monasteriata* with *M. grisea*) corroborates morphological similarities among these species. For example, both *M. capitata* and *M. verrucosa* share large coenosteum tuberculae forming verrucae and *M. monasteriata* and *M. grisea* approach each other morphologically with their coenosteum tuberculae and thecal papillae (Veron 2000).

The close relationship between the *Galaxea* spp. and *Euphyllia* spp. recovered is similar to that found by Fukami et al. (2008). Although *Galaxea* is in the family Oculinidae (Veron 2000), it likely shares a closer phylogenetic history with members of the family Euphyllidae (Fukami et al. 2008).

The "Faviidae-Siderastreidae-Agariciidae" clade contained unexpected groupings. The polyphyly of *S. radians* and *S. siderea* is an example. Given the poor statistical support for the branching topology within this clade, however, it is likely that insufficient sampling and/or the lack of phylogenetic information available at this locus resulted in the uncertain relationships found.

All of the taxa used in this analysis are considered "complex" corals except two species, *S. bournoni* and *D. labyrinthiformis* (see Romano and Palumbi 1996 and Fukami et al. 2008). Trends concerning the evolution of the "complex" and "robust' corals were, therefore, not possible. Our "Faviidae-Siderastreidae-Agariciidae" clade grouped two "robust" corals, *S. bournoni* and *D. labyrinthiformis*, with three "complex" coral species (Fig 1). The relationship of *P. speciosa* to these "robust" corals is inconsistent with Fukami et al. (2008). They recovered *P. speciosa* as a sister taxon to a clade containing *Galaxea* and *Euphyllia* spp. However, *Siderastrea* branches divergently among the "complex" corals (Fukami et al. 2008), and it is, therefore, likely that both *S. bournoni* and *D. labyrinthiformis* would share a closer phylogenetic affinity to the *Siderastrea* than to the other taxonomic groups in our phylogeny.

This study represents the first use of an organic matrix protein to reconstruct phylogenetic relationships among corals. There is still much that is not known about the gene galaxin or the biomineralization process in corals. For example, how many other genes are involved in the calcification process? And how exactly do organic matrix proteins influence morphology? The gene

galaxin is likely part of a gene family, and there are at least two galaxin-type genes indentified (D. Miller, unpub. data). It is still uncertain how these genes, and the proteins they encode, affect skeletal morphology and what they may reveal about the evolutionary history of the entire scleractinian lineage. Future work will involve complementing organic matrix loci with other established molecular markers. A complementary approach should help unravel the uncertainties of scleractinian evolution and possibly highlight areas where morphological taxonomy and molecular phylogenies have been confounding and/or add corroborative support to established relationships.

Acknowledgement

We thank Craig Starger for sequencing several of the samples, and Adrienne M.S. Correa and Rachel Silverstein for the samples from Western Australia. This work was supported by National Science Foundation BIO-OCE 0547169.

Need for a more integrative approach to scleractinian taxonomy

V.N. Zlatarski

Independent Scientist, 131 Fales Road, Bristol, RI 02809, USA

Abstract. The history of scleractinian taxonomy is divided into six periods: the original, purely typological, was based on scarce coralla material; the second, starting at the end of nineteenth century, originated with visiting natural habitat and established variability; the third commenced in the 1930s with detailed skeletal study; the fourth began in the 1950s with scuba access to coral habitat; the fifth began in the 1980s following fundamental discoveries in life history and molecular genetics; and the sixth started in 1995, when data from molecular genetics opened a new avenue for scleractinian megataxonomy, contradicting conventional gross-morphology taxonomy but resulting congruent with skeletal histology and ornamentation. Currently, there are four sources of scleractinian taxonomic information: morphology, paleobiology, developmental biology and molecular genetics. Taxonomy is important for understanding scleractinian biodiversity and reef conservation. However, the taxonomy is fragmented and the nomenclature tangled. The e-dimension benefits have not yet been realized and the New Taxonomy not yet arrived for scleractinians. Vision and teamwork are needed for a more integrative taxonomy. The Atlantic Scleractinia Initiative seeks to address the following points: massive sampling, study of the mesophotic habitat, collection access, analysis of phenotypic diversity, life history, geological history, molecular genetics, cyberinfrastructure and education of specialists.

Key words: Scleractinia, taxonomy, microstructure, biodiversity, reefs.

Introduction

For a long time, the taxonomy of scleractinians was based only on macromorphologic skeleton characters. This changed fundamentally in the second half of the last century, and even more during the last two dozen years, following a series of important discoveries related to skeletal ornamentation and histological microstructure, paleobiology, ecology, roll in the reef ecosystem, life history and molecular genetics. With new knowledge, the taxonomy became very complex, and it now plays a crucial role in the understanding of scleractinians, their biodiversity and importance for the fragile reef system.

This note provides a brief historical review of scleractinian taxonomy and an analysis of its current state, and concludes with recommendations for a more integrative approach.

History

The history of scleractinian taxonomy can be divided into six periods which demonstrate its accelerated development.

First period

Originally, studies were based on scarce coralla material found on beaches or during fishing activities, and the taxonomy was *purely typological*.

Second period

At the end of the nineteenth century, investigators began visiting the natural coral habitat. Field observations and systematized sampling demonstrated the presence of *scleractinian variability*. The forma category was introduced as a taxonomic subdivision of the species (Quelch 1886; Vaughan 1901, 1907). Transplantations first demonstrated induced change in coral growth form (Vaughan 1911). During the first half of the twentieth century, these corals did not attract much attention from zoologists. Two American paleontologists synthesized the knowledge on Scleractinia (Vaughan and Wells 1943; Wells 1956).

Third period

In late 1930s, in France, another paleontologist commenced a revision of the classical fossil coral collections, paying special attention to skeletal ornamentation and histological microstructure (Alloiteau 1952, 1957), and put together a team of specialists on scleractinians of different geological periods. The ornamentation of the radial elements was considered to reflect their histological structure and was used in the scleractinian systematic. The taxonomy was based on *more skeletal characters* than previously. Unfortunately, this improved taxonomic methodology was not applied for long outside the

disciples of the Parisian school, which may have been due to language barriers.

Fourth period

Starting in the 1950s, scuba made the *coral habitat accessible* for investigators. Pioneering work (in order of execution) in Jamaica (Goreau 1959, Goreau and Wells 1967; Wells 1973), the South Pacific (Chevalier 1968, 1971, 1975), Madagascar (Pichon 1964), the Red Sea (Scheer, 1964; Loya and Slobodkin 1971), Cuba (Zlatarski 1982) and Australia (Veron and Pichon 1976, 1980, 1982; Veron and Wallace 1984; Veron et al. 1977) established an extraordinary variability of the skeletal morphology on a global scale and shed light on the role of Scleractinia in the reef-building process. These findings coincided with the results of massive paleontological sampling of scleractinians from different geological periods, from their appearance in the Triassic to the present. The global spatial and temporal variability translated into serious taxonomic difficulties for species identification, which is basic for reef study. A reevaluation of the scleractinian taxonomy was needed (Zlatarski 2007). The last synthesis on scleractinians (Chevalier 1987) presented the enormous mass of information collected to date and the dilemmas of this period.

Fifth period

Since the 1980s, a series of *fundamental discoveries in life history and molecular genetics* broadened very quickly the existing scleractinian knowledge in uncharted aspects: long generation times and frequent propagation fragmentation (Potts 1984), simultaneous multispecific spawning (Harrison et al. 1984; Oliver and Willis 1987), reticulate concept for coral speciation (Veron 1995), lateral gene transfer or hybridization (Willis et al. 1997), astonishing growth forms in aquaria (Carlson 1999), coral symbiosis (Hoegh-Guldberg 1999), coral health and the role of microorganisms in relation to it (Rosenberg and Loya 2004; Reshef et al. 2006), and the notion of coral holobiont (Rosenberg et al. 2007). Research interest in scleractinians ceased to be focused exclusively on morphology. Instead it expanded widely in numerous new directions (Zlatarski 2007) and became an important and integral part of reef investigations. The time had come to reorient scleractinian research and for a basic change in the taxonomy.

Sixth period

So much has been learned over the past dozen years, as molecular genetics opened a new avenue for scleractinian megataxonomy (Chen et al. 1995; Veron et al. 1996; Romano and Palumbi 1996; Romano 1996; Romano and Cairns 2000). Strikingly, due to the findings of homoplasious gross-morphology characters, the results were non-congruent with the conventional taxonomy, based on macromorphologic characters. Most traditional supra-families and some families and genera were recognized not to be monophyletic units and this led to a taxonomic impasse. Not surprisingly, the solution came from the previously-introduced (during the third period) but neglected methodology of more detailed morphological study, and from rediscovering the septocentric scleractinian taxonomy (Stolarski and Roniewicz 2001; Stolarski and Russo 2002; Fukami et al. 1994; Cuif et al. 2003; Stolarski and Vertino 2007). Importantly, it turned out that *the molecular information is congruent with data of skeletal histological structure and ornamentation*.

Today

The current situation

Today there are four sources of scleractinian taxonomic information: morphology, paleobiology, developmental biology and molecular genetics. Use of all four is necessary for optimal success. Taxonomic decisions based on only a portion of the available sources are neither satisfactory nor justified. Taxonomic projects are no longer possible for the solo investigator and require teams and networks.

Fundamental biological and taxonomic issues such as species definition and the process of speciation continue to be the subject of discussion. The question of how much reproductive isolation is required between "good" species remains open (Abbott et al. 2008) and applies frequently to scleractinians. Also for these corals, phenotypic plasticity (environment-induced changes in morphology) is usually not distinguished from intraspecific genetic variation (polymorphism) (Todd 2008). The latter offers a probable explanation for the existence of some instances of morphogenesis extravaganza. For example, in environments with calm waters, a lack of hard substratum and the presence of very fine sediments, it looks like mutational accidents were not eliminated by selection, and evolution led to exuberant endemic colony astogeny. In the same train of thought, the endemic morphological richness of the Lower Cretaceous scleractinians of Diplocteniopsidae (Zlatarski 1968) is reminiscent of speculations regarding the origin of the rich Burgess shale fauna (Mayr 2001).

The taxonomy is fragmented in a number of ways and for a variety of reasons. First, some taxonomic works are purely descriptive while others have a predominantly phylogenetic orientation. Neither extreme benefits taxonomic efforts. Second, researchers rely on literature published during a very long period, the last 250 years, and it is not always

easy to access this literature. Third, the publications are in various languages, requiring a certain linguistic ability. Fourth, investigators need to study the existing collections, but sometimes these are not available or access to them is restricted. Fifth, the research facilities are frequently far from the natural habitat. In addition to all of these obstacles, taxonomists need to untangle a multitude of nomenclatural challenges.

These impediments pose serious challenges and require a reorganization of the taxonomic work utilizing all available sources as well as a mastery of professional skills, nomenclature and ethics.

The e-dimension

In the face of our current taxonomic difficulties and the gathering clouds over coral reef survival, there is a silver lining in the potential offered up by electronic communication. It has quite aptly been stated that taxonomy is made for the Internet (Godfray 2002). The cyberinfrastructure offers on a global scale not only ways for accessible and efficient communication between investigators, but it is also diminishing the disadvantages caused by the fragmentary character of taxonomy. Taxonomic work may benefit from the online availability of rare publications; digitized collections and virtual usage of types and specimens; storage of rich descriptive data and illustrations; and reduction of the distance between researchers and major institutions. The e-dimension is open to a wide audience, including "purist" taxonomists, specialists dedicated to reef conservation, educators and laymen. It permits taxonomy to be vested with authority and at the same time not to be authoritarian. The advantages of the e-dimension for scleractinian taxonomy are yet to be realized.

The New Taxonomy

The 2005 international Biennial Conference of the Systematic Association held in Cardiff, Wales a symposium entitled "The New Taxonomy," and published Special Volume Series 76 (Wheeler 2008, ed.). Participants argued for the important new role of taxonomy in the understanding and conservation of biodiversity. Attention was focused on the inadequacy of funding for taxonomic work and education; the need to support descriptive taxonomy, which is the basis of identification and phylogeny but has recently been the neglected Cinderella of taxonomy; and the urgency of e-taxonomy, networks, museum engagement, democratization of taxonomy and planetary scale projects. Taxon knowledge communities, "people with similar interests and expertise connected through cyberinfrastructure such that they may interact, collaborate and even compete with one another on a much accelerated time scale," (*ibid*.) have taken on important significance. Taxon knowledge communities lead to virtual taxon knowledge banks in which the following are available in a cost-effective and environmentally-friendly manner: literature, 3-D digitized and georeferenced specimens, identification tools, maps, field guides and all of the pertinent information from all taxonomic sources. At the present time, the international scientific community is enabling a New Taxonomy through large-scale projects and programs such as: Encyclopedia of Life (EOL), Global Biodiversity Information Facility (GBIF), Planetary Biodiversity Inventories (PBIs), Legacy Infrastructure Network for Natural Environments (LINNE), European Distributed Institute for Taxonomy (EDIT) and Creating an e-Taxonomy (CATE). The book "The New Taxonomy" is loaded with energy and vision and presents a call to arms "for the taxonomy and museum communities to come together and to organize, plan, innovate and initiate the most ambitious period of exploration in the long history of taxonomy" (*ibid*.).

Ways forward

The scleractinian taxonomy is still far from realizing the progress and advantages of contemporary taxonomic science. How this can be efficiently addressed? Taxonomic work can be oriented top-down or down-up. Both ways are useful. The latter is practiced more frequently and is more matched to everyday necessities. Teamwork can be organized on various different scales: planetary, regional or special task forces. The volume of work and the nature of species composition makes it recommendable to start regionally.

Toward an Atlantic Scleractinia Initiative

The following must be addressed for the success of a future integrative approach to Atlantic scleractinian taxonomy:

- *Massive sampling.* Comprehension of scleractinian variability and plasticity requires massive sampling, which lately is hardly ever applied.
- *Study of the mesophotic habitat*. Despite the well-established scleractinian presence in the mesophotic habitat in Jamaica (Goreau and Wells 1967), Cuba (Zlatarski 1982), Bahamas (Reed 1985), Barbados (Macintyre et al. 1991), Curacao and Bonaire (Bak et al. 2005) and Mexico (Zlatarski 2008), recent attention has mainly been focused on shallow waters.
- *Collection access*. There is much to be done. The collection of T. F. Goreau has for more than three decades remained unavailable in storage.

Among the large monograph collections, only the Cuban one is well-preserved in the National Aquarium in Havana (Zlatarski 2004), but unfortunately, for reasons beyond the control of the host institution, it is out of reach for many researchers. The corals at the Smithsonian Institution, Washington, D.C., serve as a good example of well-inventoried and available specimens. For the Atlantic province, digitized collections and virtual usage of types and specimens are not yet available.

- *Analysis of phenotypic diversity*. Knowledge of phenotypic diversity at all levels of biological organization, from structural elements to high systematic categories, is basic for taxonomic work. The phenoid delineation is a first step for making sense of taxon structure. Its usefulness became evident when taxonomic problems identified and decisions made decades ago (Zlatarski 1982) were recently validated by molecular studies (Zlatarski 2008).
- *Life history*. The insufficiency of data on the life history of Atlantic scleractinians presents an obstacle for a better understanding of the species as a basic taxonomic unit. Systematized observations and experiments in natural habitat and aquaria are needed.
- *Geological history*. The application of the reversed principle of uniformitarianism can facilitate the explanation of particular cases of evolution. For example, the presence of considerably smaller and more delicate scleractinian colonies in Golfo de Guacanayabo, Cuba, as compared to the rest of Caribbean (Zlatarski, 1982), may be viewed together with the endemic morphogenesis observed in Lower Cretaceous scleractinians of Diplocteniopsidae in Bulgaria (Zlatarski 1968). It is likely that evolution in an environment of calm waters, the lack of a hard bottom and the presence of very fine sediments resulted in a different colony astogeny in a very limited temporal and spatial range.
- *Molecular genetics*. As a new, very powerful and expensive taxonomic tool, molecular genetics should be used after the completion of a systematized sampling process corresponding to phenotypic diversity and life history traits, in coordination with interested researchers.
- *Cyberinfrastructure*. A website for Atlantic scleractinian taxonomy is needed to form a taxon knowledge community and taxon knowledge bank, and to provide easy and inexpensive access to literature, collections and all pertinent documentation for specialists and others interested in scleractinians and reefs. The experience of writing the Treatise on Invertebrate Paleontology for Scleractinia by means of a website could be helpful in designing a website for extant Atlantic scleractinians.
- *Education of specialists*. The necessity to make use of four sources of taxonomic information requires fundamental changes in educational programs in order to prepare specialists to able to meet the more stringent requirements of the New Taxonomy.

Ultimately, all of the foregoing recommendations will be fruitless in the absence of a collaborative spirit in forging strategies and working together in the most efficient and integrative way. This is especially important at a time when taxonomy plays such a crucial role for the understanding of scleractinian biodiversity and the conservation of coral reefs.

Acknowledgement

I am grateful to Dr. John W. ("Wes") Tunnell, Jr. of the Harte Research Institute for Gulf of Mexico Studies and Center for Coastal Studies of Texas A&M Univ., Corpus Christi, to the Organizers of the 11th ICRS, and to Dr. V. Kosmynin, for their moral support and assistance in attending the Ft. Lauderdale event. I also thank Mrs. K. Beaird of the Barrington Public Library in Rhode Island for helping me to obtain necessary publications and my daughter Vera for improving the English.

Abstract. Species richness is a common measure of biodiversity, but offers only a partial view of the assemblages. Morphological diversity is another indicator, and can reflect functional aspects of the system more efficiently than the number of taxa. In this study we compared patterns of richness and morphodiversity in the genus *Porites* in the Pacific Ocean. Distribution data of 52 species were arranged in quadrants of 20° of latitude and longitude, and nine morphological characters were measured for each species. The latter data were processed with a principal components analysis, and the diversity of forms was estimated from the geometric mean of the range of the scores of each component. We found out that richness in this genus is concentrated in southeastern Asia, but morphodiversity is more widely distributed and high values appear indistinctly if species number is high or low. The relationship between richness and morphology in *Porites* followed a logarithmic curve and tend to reach an asymptote, and there were no significant differences in morphodiversity of the hemispheres or between the tropics and subtropics. We suggest that the observed morphospace limitations in *Porites* may indicate saturation in niche availability, or occur because of the existence of phyletic boundaries.

Key words: coral, Porites, Pacific Ocean, morphology

Introduction

Biological diversity is a complex property that can be measured using any of many traits, from genetic diversity to landscape variety, as each of them offers a different perspective of the phenomenon (Wilson 1996). The most common organization level at which biodiversity has been quantified is the community, and in this case researchers usually focus on species richness as the concept is easy to grasp by the general public and it is intuitively "natural" (Gaston and Spicer 2004). Studies performed in the last decade show that richness tend to correlate well with other biodiversity predictors, and even between different taxonomic groups (Roberts et al. 2002; Qian and Ricklefs 2008). However, in some cases the richness behaves differently to specific and important indicators; for example is not much related to endemism both in the land and marine realms (Hughes et al. 2002; Orme et al. 2005), and because of that situation some authors have called attention to avoid focusing all efforts to preserve only rich areas (Kareiva and Marvier 2003)

One predictor that seems to correlate well with marine species richness is morphological diversity (Roy et al. 2000). The latter has traditionally been considered as a key tool for paleoecological reconstruction (Foote 1992), and other studies have demonstrated its application for the better understanding of the ecological functioning in Recent coral reefs (Bellwood et al. 2006), gastropod evolution (Latioalis et al. 2006), and comparison of niche space utilized by gastropods living at different depths (McClain et al. 2004). The good fit between form and function was well received because in turn, morphology can reflect the functional aspects of the marine ecosystems very efficiently (Wainwright 2007) as it recognizes particular traits of each species; thus, species richness could be applied as an efficient proximal indicator of ecological functions performed by a certain taxonomic group.

However, not all papers coincide that richness and morphology follow a common trend. For example, Foote (1993) found no relationship or clear trend between richness and morphological diversity in trilobites, and in recent marine organisms the number of species of strombid snails turns out to be a poor indicator of morphological diversity in the Indo Pacific (Roy et al. 2001), basically because certain areas with low richness had a high morphological diversity. Other examples of this situation are cuttlefishes, in which richness and morphological diversity and disparity are independent (Neige 2003).

Corals have a long history of morphological analyses, especially related to taxonomy and phylogeny (Powers and Rohlf 1972; Hoeksema, 1989; Weil et al. 1994), but recently the focus has shifted to more functional aspects related to metabolism, light gathering and others (Enríquez et al. 2005; Todd 2008; Hogenboom et al. 2008). Considering this change of perspective, the objective of this work was to compare the patterns of species richness and morphological diversity in the coral genus *Porites,* as a way to provide a different view of the biodiversity of the taxon. This genus has 60 species (Carpenter et al., 2008), a worldwide distribution and is one of the most conspicuous in reefs. It is also recognized by its ecological role as reef builder and habitat to many species of invertebrates and fishes (Veron 2000).

Methods

To determine species richness of *Porites*, we used the information of 52 species appeared in Veron (2000), and updated it with records from more recent papers. The data (presence-absence) were arranged in quadrants of 20° of latitude and longitude, which covered the entire Pacific Ocean (N=48), and a distribution matrix was completed from where richness was calculated by simple sum.

The morphological study involved nine characters that were measured in museum specimens or from photographs: maximum and minimum corallite (taken as an ellipse), number of septa, number of pali, depth of calices, width of corallite wall, size of columella, ration between depth of calice, and maximum diameter, and type of colony (massive, encrusting or ramose). All measures were taken with a precision of $\pm$ 1 mm, and in a minimum of five corallites or images. The set of measurements was standardized (mean= 0, SD = 1) and processed with a principal component analysis, using a covariance matrix (Bakus 2007). This technique allowed the construction of a multidimensional morphospace (Fig. 1) from where we used the geometric mean of the range of the scores of each component to measure the extent of morphological space occupied (Roy et al., 2000, McClain et al., 2004). The last calculation was performed on the data of present species in each quadrant. Finally, a one way ANOVA test (Zar 1999) was applied to look for differences in morphological diversity between hemispheres (north and south), and latitudes (0° to 20°, and 21° to 40°, independent of the hemisphere)

Results

The Fig. 1 shows the empirical morphospace (axis I and II) calculated for the 52 *Porites* species, and we present sketches of the general morphology at each side of the plot. In specific, the left upper corner has species with a platy morphology (e.g., *Porites tuberculosa* Veron, 2000, *P. densa* Vaughan, 1918), at the upper right we found the ramose species (*P. rugosa* Fenner and Veron, 2000*, P. flavus* Veron 2000), and at the bottom those with encrusting and columnar colonies like *P. solida* Forskaal 1775 and *P. heronensis* Veron, 1985, respectively.

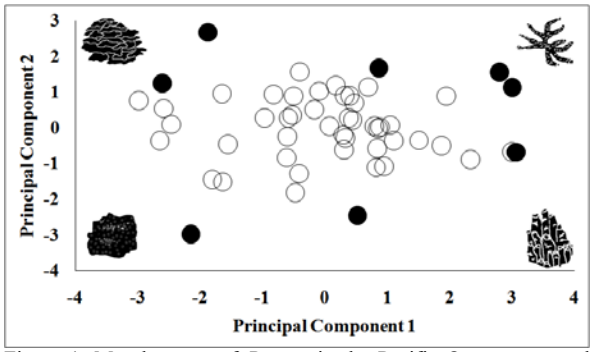

Figure 1. Morphospace of *Porites* in the Pacific Ocean, prepared with principal component analysis.

The map of species richness (Fig. 2) shows that as expected, the highest values can be found at southeastern Asia (over 26 species, and as much as 31), followed by Japan, the Indian Ocean and the Great Barrier Reef (21 to 25). In contrast, the lowest richness occurs in South America, Easter Island and other eastern Polynesian islands, and near the entrance of the Persian Gulf. As it occurs with many marine species, and in particular with corals, there is a clear gradient from the center of marine diversity around Indonesia and Papua New Guinea, to the central and eastern Pacific (Bellwood and Hughes 2001; Roberts et al. 2002).

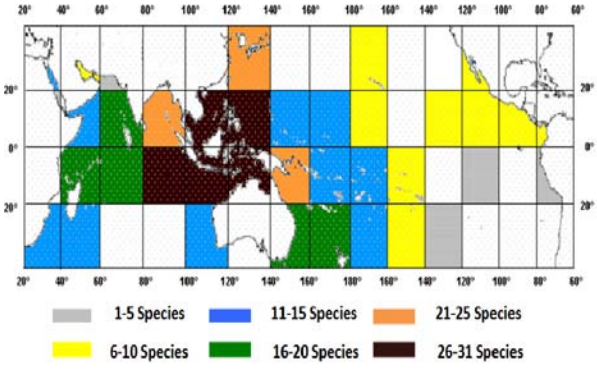

Figure 2. Species Richness of genus *Porites* in the Pacific Ocean.

The situation of morphological diversity was very different (Fig. 3). The index had its highest values in areas including the east coast of Africa, the central Pacific and the equatorial Indian Ocean. It was also

high at the entire north and east coast of Australia and New Caledonia. Interestingly, the areas with lowest morphodiversity (South America and east Polynesia) coincide much more with the results in Fig. 2

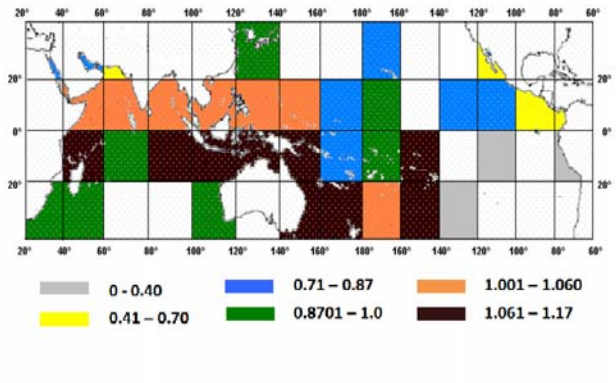

Figure 3. Morphological diversity of the genus *Porites* in the Pacific Ocean.

Comparing species richness and morphological diversity, we can observe that the relationship is not linear, but follows a logarithmic curve. When richness is low 0 to 10 species), the complexity of forms in each quadrat of 20 square degrees rises fast, but in areas where richness is higher than that, the morphodiversity tends to flatten. Also notice that the site where the variety of forms is highest (1.089; eastern Polynesia), there are only seven species present.

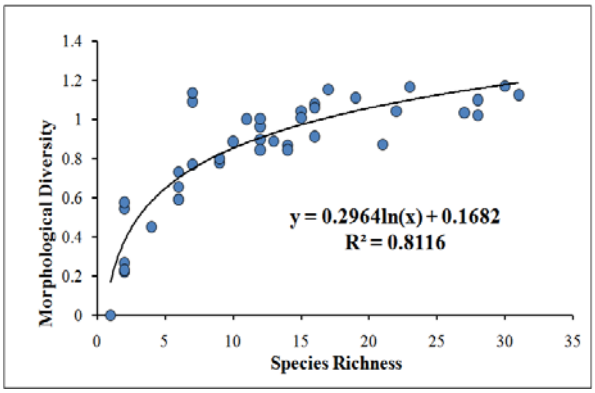

Figure 4. Species richness and morphological diversity in *Porites*. The regression was significant.

To test if sites where richness was higher than 10 can have an effect on morphology, we run a Student t test to compare areas with 10 to 20 species with those having 21 or more. and the result indicated no significant differences ($t_{25} = 1.15$, $p > 0.10$). In short, our analyses indicates that morphological diversity in the genus *Porites* do not increases in proportion to species richness, and that it may exist an upper limit to this biodiversity measure in the Pacific Ocean.

The comparisons between hemispheres (Fig. 4) indicated that richness of *Porites* per site was higher in the Southern Hemisphere than in the Northern ($t_{25} = 3.21$, $p < 0.01$), but that morphodiversity did not differ ($t_{25} = 2.07$, $p > 0.05$). In the case of latitude (Fig. 5), the number of species per site also differed as areas north of 20° N and S were richer ($t_{25} = 5.43$, $p < 0.001$), but as it happened previously, the morphodivesity did not differ between tropical or subtropical zones ($t_{25} = 1.21$, $p > 0.05$).

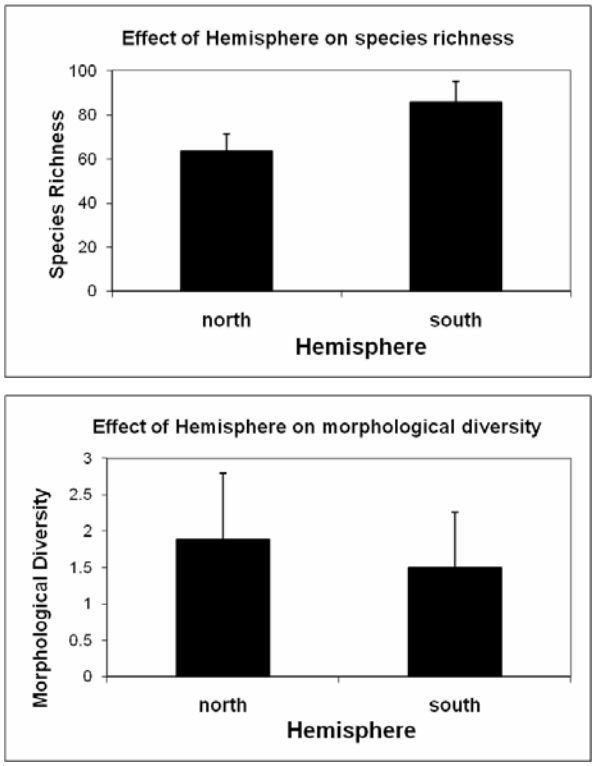

Figure 4. Comparison of richness and morphodiversity of *Porites* between hemispheres in the Pacific Ocean.

Discussion

As shown, morphological diversity and species richness of *Porites* corals behave independently. The scenario that richness generate a variety of forms (and consequently that the relation should be monotonic, or at least positive) has been tested and found in studies of terrestrial animals (Williams and Humphries 1996; Roy and Foote 1997) but nevertheless it does not seem to be the dominant pattern in the marine realm, as it was not found either in gastropods (Roy et al. 2002), sea urchins (González-Azcárraga 2008) or corals (this study). This finding is not necessarily bad news; on the contrary, we propose that the fact that richness and morphodiversity are complementary opens a new

avenue of research in the future, with important ramifications for conservation and functional studies in reef ecosystems.

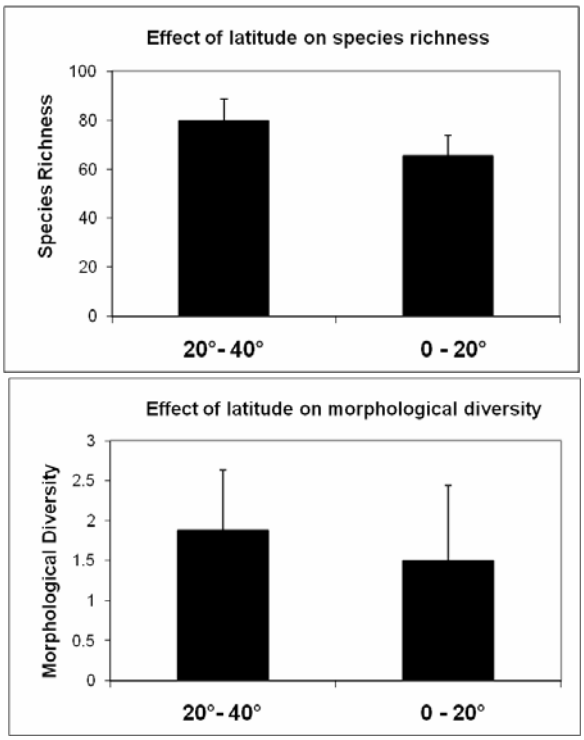

Figure 5. Comparison of richness and morphodiversity of *Porites* between hemispheres in the Pacific Ocean.

In Fig. 3 it is apparent that some regions with few species have remarkably high morphological diversity, including peripheral areas like Polynesia and east Africa. A more in-depth examination should be done, but it is possible that these anomalous areas have at least one endemic species, or a coral with an unusual collection of characters, so the value of the variance in form is increased. However if we consider the Pacific as a unit, morphodiversity in *Porites* is remarkably homogeneous and it seems not to be much influenced by latitude or hemisphere (Figs. 4-5).

Maybe the most important result of the study was the comparison of richness and morphology, which point out that even when both indicators move almost linearly near the axis, the latter eventually tend to reach an asymptote (Fig. 4). This pattern can be explained either from the evolutionary or ecological perspective. In the first one, the genus *Porites* might actually have a phyletic limit in its variety of forms and design (its bauplan), and thus it should be independent of richness. If this idea is correct, a study on fossil species may found that the genus has been transforming in time, and becoming more complex in its calicular and colonial structure. On the other hand, the limitation in morphology may result if the environment is providing only a limited kind or amount of resources, so that eventually result in saturation of niche availability. There have been many discussions on the size of the niche of hermatypic corals, and of the factors that determine it (Connell 1978; Knowlton and Jackson 1994; Iglesias-Prieto et al. 2004), but the authors coincide that as scleractinians are specialists, its ecological space should be restricted. This observation could explain our results, but there still are many questions to be addressed before obtaining a firm conclusion. Whatever the case, the use of morphological diversity as an indicator of biodiversity of reef corals show promise and should be pursued in future research.

Acknowledgments

We thank the comments by J.E.N. Veron (AIMS) and G. Paulay (University of Florida) about the quality of the database and efficiency of methods. S.D. Cairns (Smithsonian Institution) allow the unrestricted us of the collections in the National Museum of Natural History, and provided literature and illustrations of several species. Saul González (UABCS) took photographs and collaborated in the processing of images. Abstract. A preliminary ecological assessment of coral communities was conducted in Cabo Verde (North Atlantic). Two fieldtrips recorded underwater transects with DAFOR semi-quantitative scale to estimate relative abundance of coral species. This effort, together with a review of historical records, allowed a preliminary identification and description of three major coral biotopes: i) antipatharian facies in vertical walls; ii) *Siderastrea radians* pavements over shallow bedrock; and iii) diverse coral coverage over rocky reef with sand patches. Coral species diversity in these biotopes is lower than in other tropical reef ecosystems. Sal Island, where a more extensive survey was possible, revealed greater living coverage and biodiversity on the leeward side when compared with the windward side of the island. Depth and hard substratum orientation (vertical/horizontal) appear to act as major environmental factors structuring communities in these biotopes. The importance of other factors affecting their distribution, structure and diversity, such as water temperature, West African upwelling influence and dust deposition from Sahara desert, by prevailing and Harmattan winds, are briefly discussed.

Key words: Ecological assessment, coral diversity, biotopes

Introduction

Sited at 15.02N, 23.34W, the Cabo Verde archipelago comprises ten islands and five islets located about 300 nautical miles WNW off the coast of Dakar, Senegal (Fig. 1). Volcanic in origin, the islands rise from the deep abyssal plain beyond the African continental shelf.

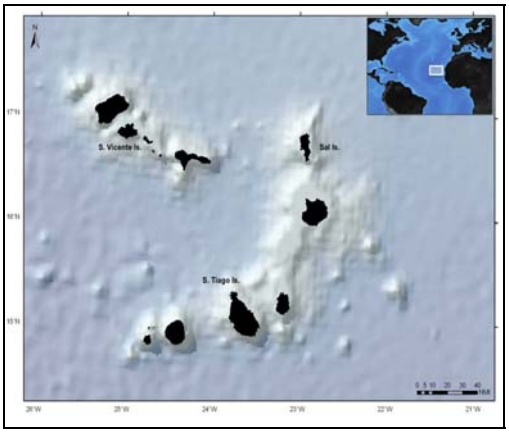

Figure 1: Geographical location of Cabo Verde Islands.©*Imag*DOP

These islands are considered to be an important hotspot of tropical reef biodiversity and one of the top ten priority locations worldwide for the conservation of reef habitats (Roberts et al. 2002). Despite the absence of major coral reef structures and of the relatively low richness of coral species and reef-associated fauna, these islands' coral communities constitute unique habitats as many species display a small distributional range (Laborel 1974; Moses et al. 2003; Roberts et al. 2002).

These coral communities are of major importance for coastal ecosystems (providing habitat and supporting other fauna and flora) and play a key role on the sustainability of local fishing and economy (Wells 1988; Wilkinson 2004).

Recent efforts to characterize coral communities and associated fauna and flora have been conducted in specific locations of São Vicente Island (Delgado 2006) and Sal Island (Henriquez et al. 2006). Although providing valuable information and extensive lists of coral species and associated fauna and flora, studies are site restricted and lack a uniform approach that relates species composition and its variance to environmental conditions.

The goal of the present work was a preliminary ecological assessment of coral communities in Cape Verde Islands, setting the basis for the experimental design of a more detailed characterization of these coral communities. Determining the species composition and its variance within and between locations, related to physical and environmental parameters and gradients, such as depth and substratum nature and orientation, allows one to determine areas of uniform environmental conditions providing a living place for a specific

assemblage of organisms (Jokiel 2002; Wallenstein and Neto 2006). Accordingly, accessing i) conspicuous coral species, relative abundance and distribution and closely associated species composition, and; ii) major physical and environmental parameters/gradients determining coral distribution, provided valuable data and information to identify major coral communities' biotopes and produce the necessary background for following characterization of these communities.

Material and Methods

Fieldwork conducted in Cabo Verde included two survey missions (November and July 2007) at three islands (Fig. 2) where coral communities had been reported by Laborel (1974) and Moses et al. (2003). Within each location, five sites were selected and surveyed using depth and substratum nature and orientation (horizontal/vertical) as major determining factors conditioning coral and associated species' composition and distribution limits.

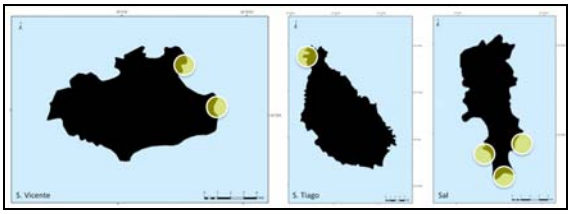

Figure 2: Visited locations during survey missions to S. Vicente Is. and S. Tiago Is. (July 2007) and Sal Is. (November 2007)©*Imag*DOP

Each site was surveyed (using SCUBA) with four underwater transects, parallel to a depth gradient between 5 and 20 meters of depth. Transects were randomly distributed using a two digit random number table. The first digit determined the direction of following placement: heading towards the shore, an even first digits meant the following transect would be placed to the right and odd digits meant it would be placed to the left of the previous transect (first transect placed in relation to the start point of the dive). The second digit determined the distance, in meters, for the placement of the following transect (first transect placed in relation to the start point of the dive). For example (Fig. 3), having the first transect ended at 20 m, the random number 27 would mean that the following transect would start at that depth, 7 meters to the right (heading shoreward). Whenever transect placement would fall outside hard bottom substratum with coral coverage, the following random number would be considered.

Coral species relative abundance was accessed with DAFOR (**D**ominant, **A**bundant, **F**requent, **O**ccasional and **R**are) semi-quantitative scale (Hawkins and Jones 1992, Wallenstein and Neto 2006), at each 5 meters of depth. Conspicuous associated fauna and flora composition substratum nature and orientation was also accessed throughout these transects. Hard bottom substratum, where coral occurs, was classified into three categories: i) bedrock, ii) bedrock patches and boulders over sand bottom, and iii) vertical and sub-vertical walls. DAFOR values were averaged from transects over the three major kinds of substratum where coral species occur for overall values.

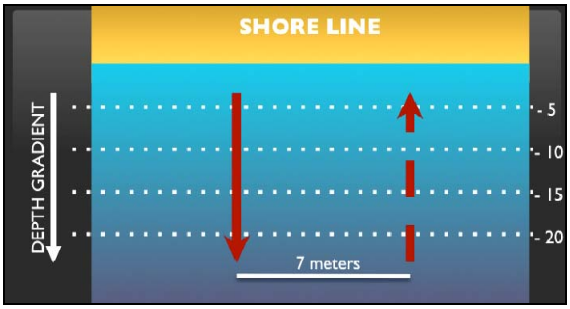

Figure 3: Scheme of two consecutive transects' placement using a random number equal to 27. Second transect (dashed) start point placed 7 meters to the right of previous transect end point.

Results

Biological data against depth, bottom type and orientation suggested that these physical parameters determined local coral species composition and limits. Restricted to hard bottom substratum, coral species distribution and DAFOR values were fit into the three categories of hard bottom substratum. Raw transect data were averaged within each category and depth (Table I). These values refer exclusively to coral species, describing relative abundance within this group.

Based on depth gradient, bottom type, orientation, as well as coral species composition, distribution and relative abundance, three different biotopes were identified:

Shallow Rocky Reef

Rocky platforms, reefs and bedrock between -4 m and -10m were clearly dominated by *Palythoa caribaeorum*, which overgrew several other coral species such as *Porites astreoides* and *Siderastrea radians. Millepora spp, Porites spp.* and *Siderastrea spp.*. *P. caribaeorum* dominance was clearest at Sal Is. and less so at other islands, where the species was dominant or abundant but did not overgrow other corals.

Siderastrea Pavements

Sandy bottom substratum, with bedrock patches and medium boulders, between -5 m and -15 m (occasionally to -20m), restricted to sheltered bays. A clear *Siderastrea spp*. dominance, forming pavements over almost all available hard substratum.

Table 1: Coral species relative abundance over different substrata (overall DAFOR values, D=Dominant, A=Abundant, F=Frequent, O=Occasional and R=Rare). * On the bottom edges over sand.

	Bedrock Reef				Bedrock patches and boulders				Vertical wall			
	5 m	10 m	15 m	20 m	5 m	10 m	15 m	20 m	5 m	10 m	15 m	20 m

MILLEPORINA												
Millepora spp.	A	O	-	-	O	F	R	-	R	-	-	-

Occasional presence of *Porites spp., Favia fragum,* and *Schizoculina africana*. Presence of *Leptogorgia spp,* over sand at the edges of hard substratum.

Walls

Vertical and subvertical facies between -10 and -20 m were dominated by antipatharians with low or no presence of scleractinians other than *Tubastrea spp.* that were abundant at lower depths, in crevices and other places with low lighting. *Leptogorgia spp.* was common over sandy bottom close to the lower edge of these walls.

Associated Fauna and Flora

Qualitative assessment of associated fauna and flora showed a clear dominance by *Dictyota spp.* and a strong presence of *Asparagopsis taxiformis* over horizontal hard bottoms. *Caulerpa sp.*, *Codium sp.* and cyanophytes were similarly abundant over bedrock patches with sand deposition. Conspicuous fauna within these biotopes include the sponges *Aplysina aerophoba* and *Chondrosia reniformes*, the gastropod *Stromba sp.,* nudibranchs *Hypseledoris spp.* and the polychaete *Hermodice carunculata.* Ichthyofauna over horizontal substrata included *Myripristis jacobus*, *Coris julis*, *Chromis multilineatus*, *Synodus saurus*, *Sparisoma cretense.* On vertical walls *Myripristis jacobus, Aulostomus strigosus, Sargocentron hastatum* and *Gymnothorax miliaris* were the most abundant species.

Discussion

This preliminary ecological assessment reveals importance of depth, type of substratum and orientation on community structure (Veron 2000; Wells 1988; Wilkinson 2004). Surveys at Sal Is. suggest a difference between living coverage on the leeward and the windward sides of the island. Factors such as temperature might be acting on a local scale due to prevailing currents. Wind regime, West African upwelling and currents together with cyclic Harmattan winds (blowing offshore from the African mainland) may cause significant deposition of dust on the windward (East) side of the island, with an impact on turbidity and light penetration in the water (Moses et al. 2003; Shinn et al. 2000) besides the negative effect of sedimentation on the organisms. The dominance and overgrowth of *P. caribaeorum* was striking at some sites. This species is known for its resilience and for smothering other corals by overgroth (Suchanek 1981). It may thus be a potential hazard for local coral communities and should be monitored.
